CHAPTER 61

Diffuse Cystic Lung Diseases

Nishant Gupta
Tami J. Bang
Kathryn A. Wikenheiser-Brokamp

INTRODUCTION

The diffuse cystic lung diseases (DCLDs) are a diverse set of disorders that share a common radiologic phenotype of thin-walled parenchymal lucencies.[1] Although often grouped together with other interstitial lung diseases (ILDs), the underlying pathobiology, differential diagnosis, mode of presentation, and natural history of disease progression in DCLDs are sufficiently distinct to warrant classification of DCLDs as a separate independent entity.[2] The subsequent sections of this chapter will provide an overview of the classification and differential diagnosis of DCLDs; detail the clinical, radiologic, and histopathologic features of various DCLDs; and culminate with an integrated approach toward the appropriate diagnosis and management of patients presenting with DCLD.

DEFINITION OF PULMONARY CYST

A pulmonary cyst is defined radiologically as a thin-walled (<2 mm wall thickness) parenchymal lucency interfaced with normal pulmonary parenchyma.[3] Table 61-1 lists the other parenchymal lesions that can mimic cysts and need to be carefully distinguished from cysts. Pathologically, cysts are defined as dilated spaces within the lung tissue that have an epithelial lining. Lung cysts may contain fluid or gas. Dilated spaces without an epithelial lining are referred to as pseudocysts and must be distinguished from true epithelial-lined lung cysts. Some lesions designated as cysts clinically and radiologically may not represent true cysts pathologically; the most common cyst mimics are bronchiectasis, honeycomb remodeling, pulmonary interstitial emphysema, centrilobular emphysema, α1-antitrypsin deficiency, and cavitary lesions.

CLASSIFICATION OF DIFFUSE CYSTIC LUNG DISEASES

DCLDs can be classified into subcategories depending upon the underlying pathogenesis (Table 61-2). However, as highlighted in Fig. 61-1, there can be substantial overlap among the pathogenesis of these entities, and thus some DCLDs could be classified under more than one category.[2]

GENETIC/DEVELOPMENTAL/CONGENITAL DIFFUSE CYSTIC LUNG DISEASES

Below we consider Birt-Hogg-Dubé syndrome, as well as other genetic and developmental diffuse cystic lung diseases.

■ Birt-Hogg-Dubé Syndrome

Birt-Hogg-Dubé syndrome (BHD) is a rare, autosomal dominant disorder characterized by the formation of hair follicle tumors (fibrofolliculomas), kidney tumors, and pulmonary cysts.[4] The initial description of this syndrome was provided by Hornstein and Knickenberg in 1975,[5] followed by the depiction of characteristic skin fibrofolliculomas and autosomal dominant inheritance pattern by Birt, Hogg, and Dubé two years later.[6]

Pathogenesis

BHD is caused by loss of function mutations in the *folliculin (FLCN)* gene, located on the short arm of chromosome 17.[7–9] *FLCN* functions as a tumor suppressor gene, and loss of heterozygosity following a somatic second hit in patients carrying a germline mutation in *FLCN* predisposes them to the formation of BHD renal tumors.[10] Similar findings have been reported in multiple animal models of BHD,[11–14] and the restoration of wild-type *FLCN* expression has been reported to halt oncogenesis in an in vitro cell line–based model.[15]

Multiple different mechanisms have been postulated to drive the tumor suppressor properties of *FLCN*,[16] chief among them being the modulation of the mechanistic target of rapamycin (mTOR) signaling pathway. mTOR is a central regulator that controls the cellular response to multiple environmental stimuli. Dysregulated mTOR signaling is responsible for the development of a related DCLD, lymphangioleiomyomatosis (LAM, covered in detail in Chapter 60). FLCN has been shown to modulate mTOR activity via its interaction with two proteins,

TABLE 61-1 Radiologic Definition of Pulmonary Cysts and Other Parenchymal Lucencies That Can Mimic Cysts

Cyst	Thin walled (<2 mm), spherical parenchymal lucency interfaced with normal lung
Cavity	Gas-filled space within pulmonary consolidation, mass, or nodule, typically thick walled (>2 mm) and more irregularly shaped than cysts
Bulla	Spherical focal lucency, ≥1 cm in diameter, bounded by a thin wall (<1 mm); usually accompanied by emphysematous changes in the adjacent lung
Bleb	Cystic air space bounded by a thin wall adjacent to the visceral pleura, typically <1 cm in size.
Emphysema	Permanently enlarged airspaces distal to the terminal bronchiole with destruction of alveolar walls; usually without visible walls
Pneumatocele	Approximately round, thin-walled, air-filled space in the lung; most frequently caused by infections, trauma, or aspiration of hydrocarbon fluid and usually transient
Honeycombing	Clustered cystic air spaces, typically 3–10 mm in diameter, with 1- to 3-mm wall thickness, that are often stacked on top of each other in layers; usually subpleural and associated with other features of pulmonary fibrosis such as traction bronchiectasis and reticulations
Bronchiectasis	Localized or diffuse bronchial dilatation, usually resulting from chronic infection, proximal airway obstruction, or congenital bronchial abnormality

TABLE 61-2 Classification of Diffuse Cystic Lung Diseases

Genetic/developmental/congenital
- Birt-Hogg-Dubé syndrome
- Phakomatoses—Cowden syndrome, neurofibromatosis, proteus syndrome
- Connective tissues diseases—Marfan syndrome, Ehlers-Danlos syndrome (type IV)
- COPA syndrome
- Down syndrome/trisomy 21
- Congenital pulmonary airway malformation, bronchopulmonary dysplasia

Associated with lymphoproliferative disorders
- Lymphoid interstitial pneumonia
- Follicular bronchiolitis
- Castleman disease
- Lymphoid granulomatosis
- Amyloidosis
- Light chain deposition disease

Neoplastic
Low-grade malignancies
- Lymphangioleiomyomatosis—sporadic as well as associated with tuberous sclerosis complex
- Histiocytosis
    - Pulmonary Langerhans cell histiocytosis
    - Non–Langerhans cell histiocytoses such as Erdheim-Chester disease, Rosai-Dorfman disease

High-grade malignancies
- Primary pulmonary neoplasms
    - Non–small-cell carcinomas
    - Mesenchymal cystic hamartoma
    - Pleuropulmonary blastoma
    - Lymphoma

- Sarcomas
    - Angiosarcomas
    - Osteosarcomas
    - Synovial sarcoma
    - Ewing sarcoma
    - Leiomyosarcoma
    - Rhabdomyosarcoma
    - Endometrial stromal sarcoma
    - Wilms tumor
    - Pineal teratoma
    - Other sarcomas

- Metastatic epithelial tumors
    - Adenocarcinomas of the gastrointestinal and genitourinary tract
- Systemic malignancies
    - Lymphoma

Infectious
- *Pneumocystis jiroveci* pneumonia
- Staphylococcal pneumonia

folliculin interacting protein 1 (FNIP1) and FNIP2, and the 5’ AMP-activated protein kinase (AMPK).[17,18] However, the relationship between *FLCN* downregulation and mTOR dysregulation is complex, with studies showing evidence of activation as well as suppression, suggesting the possibility of cell context–dependent interactions between *FLCN* and mTOR.[11,14,17,19–21] *FLCN* has also been reported to regulate mTOR activity via other mechanisms such as by activating the RagC and RagD GTPases, leading to the phosphorylation of transcription factor EB (TFEB)[22] and amino acid–dependent lysosomal mTOR activation through regulation of the heterodimers Rag A/B and Rag C/D.[23–25] Other pathways that have been implicated in the tumor suppressor action of *FLCN* include modulation of canonical Wingless-related integration site (WNT) signaling,[26] vesicle membrane trafficking via structural similarities to the differentially expressed in normal cells and neoplasia (DENN) domain proteins,[27] transforming growth factor β (TGF-β) signaling,[15] regulation of mitochondrial gene expression,[28,29] modulation of autophagy,[30,31] and activation of the transcription factor E3 (TFE3).[32]

The mechanisms driving the formation of pulmonary cysts in BHD are not well established. Postulated mechanisms to date include alterations in cell–cell adhesion,[33,34] modulation of the mTOR

pathway,[33] increased vulnerability of the alveolar septal regions to the mechanical stress of respiration,[35] and *FLCN*-dependent effects on WNT signaling.[26] Two independent laboratories have described a relationship between *FLCN* and the adherens junction protein p0071,[34,36] suggesting the possibility that impaired cell–cell adhesion drives abnormal elastance and pulmonary cyst formation in BHD. In a murine model of BHD, Goncharova et al.[37] demonstrated that loss of *Flcn* leads to alterations in the E-cadherin–dependent epithelial cell–cell junctions, impairment of liver kinase B1 and AMP-activated protein kinase (LKB1-AMPK) signaling, caspase-dependent apoptosis of lung alveolar epithelial cells, and alveolar airspace enlargement, thus supporting a role for *Flcn* in the maintenance of epithelial cell–cell junctions and alveolar epithelial cell survival. More recently, it has been shown that loss of *FLCN* inhibits canonical WNT signaling, suggesting that the formation of pulmonary cysts reflects a defect in normal lung development.[26] Further work is needed to fully elucidate the molecular mechanisms that cause the formation of lung cysts in BHD.

Clinical Manifestations

Extensive phenotypic variability exists in the clinical presentation of patients with BHD. Patients can present with any combination of pulmonary, renal, or skin manifestations.

Cutaneous Although fibrofolliculomas, trichodiscomas, and acrochordons were described in the initial depiction of BHD,[6] the characteristic skin lesion in BHD is a fibrofolliculoma. Fibrofolliculomas are benign hair follicle tumors that present as multiple dome-shaped whitish papules most commonly seen on the face, neck, and upper torso (Fig. 61-2A). Fibrofolliculomas are seen in more than 85% of individuals affected with BHD and usually appear in the third decade of life.[4,38,39] Although other skin lesions such as angiofibromas, lipomas, and others have been described in patients with BHD, these skin lesions are not specific to BHD.[38–40]

Pulmonary The major pulmonary manifestation of BHD is the formation of thin-walled cysts. Pulmonary cysts are seen in greater than 80% of patients with BHD.[38,41–44] Although reported in all age groups, including children,[45,46] pulmonary cysts in BHD are most commonly discovered in the fourth decade of life.[4] The cysts in BHD typically involve less than 10% of the pulmonary parenchyma and do not tend to produce symptoms such as dyspnea on exertion or cough that are typical of other chronic lung diseases. Pulmonary function tests (PFTs) in patients with BHD are generally well preserved and do not tend to deteriorate over time.[43,47]

The major clinical presentation resulting from pulmonary cysts in BHD is the occurrence of a spontaneous pneumothorax, that usually manifests with sudden onset dyspnea and sharp pleuritic

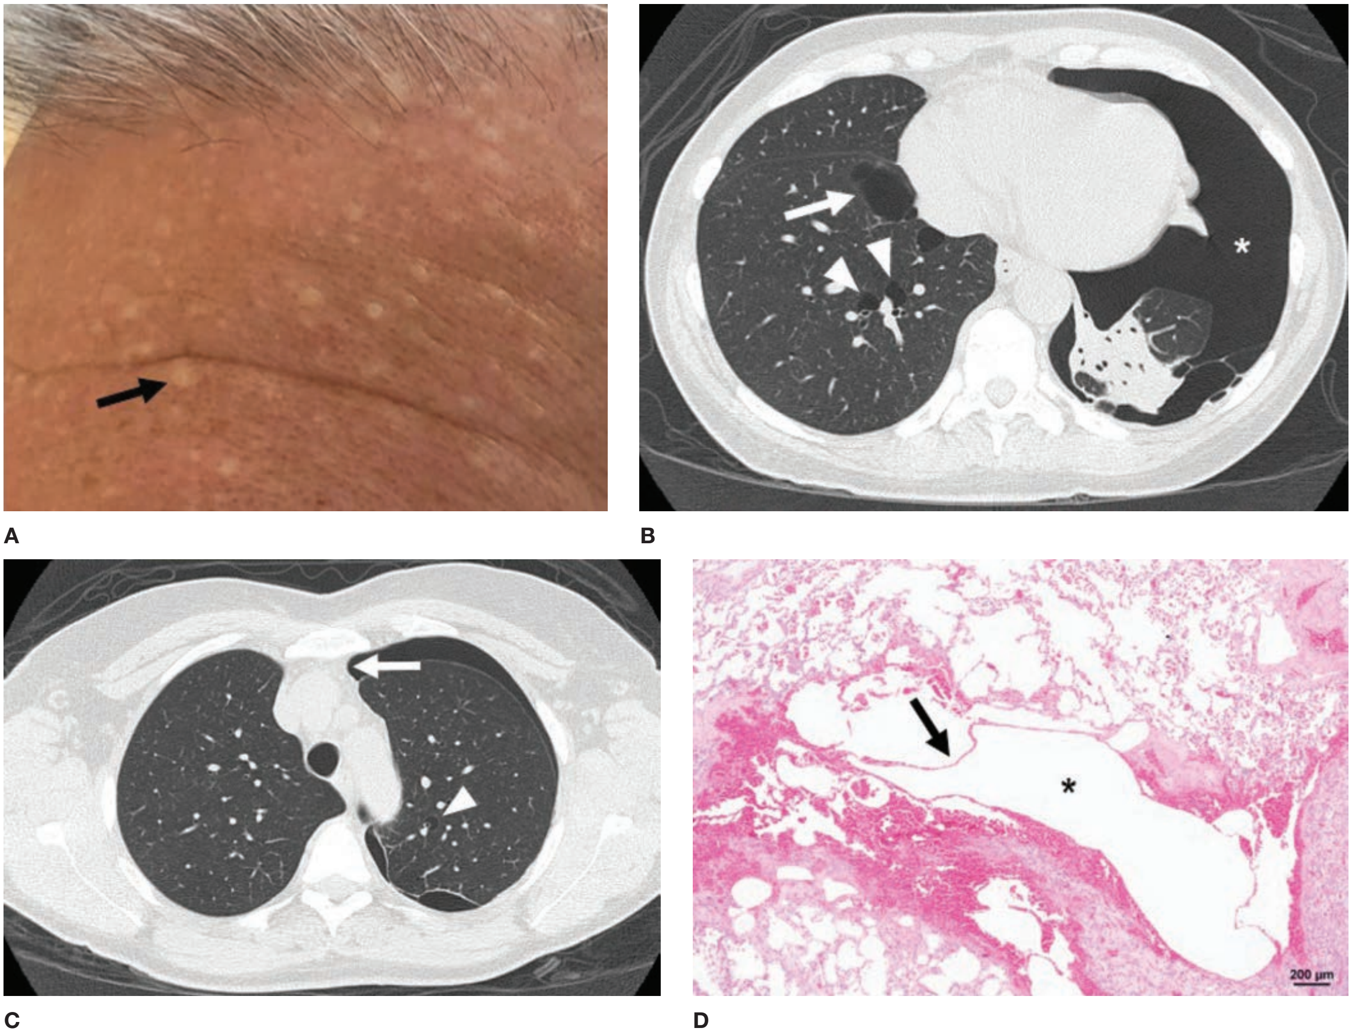

Figure 61-2 Clinical, radiologic, and histopathologic manifestations in Birt-Hogg-Dubé syndrome (BHD). **A.** Multiple, dome-shaped, whitish papules consistent with fibrofolliculomas on the forehead of a patient with BHD. **B.** Axial CT image of the lung bases in a patient with BHD demonstrating a lentiform, subpleural cyst with an internal septation *(arrow)* and perivascular cysts *(arrowheads)* in the right lower lobe. A left pneumothorax *(*)* also is present. **C.** Axial CT image from another patient showing a cyst encircling a bronchovascular bundle referred to as the air-cuff sign *(arrowhead)*. Also present is a left pneumothorax *(arrow)*. **D.** Histologically, the pulmonary cysts *(*)* in BHD have a thin wall lined by normal-appearing alveolar type I and type II epithelial cells with some cysts containing internal septations *(arrow)*. The surrounding lung parenchyma has procedure-related acute hemorrhage but is otherwise unremarkable and without significant inflammation or fibrosis as is characteristic of BHD associated lung cysts.

chest pain. Although most commonly unilateral, bilateral spontaneous pneumothorax has been reported in a minority (~5%) of cases of BHD.[42] Pneumothorax has been reported to occur in 25% to 75% of patients with BHD.[41,42] This wide range in pneumothorax occurrence can largely be explained by ascertainment bias; the 25% estimate is derived from BHD patients presenting to a dermatology/urology center,[41] and the 75% estimate is derived from a pulmonary network report.[42] The average age at the time of development of spontaneous pneumothorax in BHD is in the mid to late 30s.[41,42] There is no known gender predilection. It has been estimated that patients with BHD have a 50-fold higher risk of developing a spontaneous pneumothorax compared with age-matched healthy controls.[48] In two small studies, BHD has been estimated to be the underlying etiology for 5% to 10% of apparent primary spontaneous pneumothoraces.[49,50] Spontaneous pneumothoraces have also been reported in patients with BHD without radiologically apparent cysts on chest imaging.[51] There is an extremely high risk of recurrence (~75%) in BHD patients with a spontaneous pneumothorax.[41,42]

Renal Patients with BHD are at an increased risk of developing renal tumors that can frequently be bilateral and multifocal.[48] Approximately one-third of patients with BHD develop at least one renal tumor, with the average age at diagnosis being around 50 years.[38,44]

Other A variety of other manifestations such as thyroid nodules,[44] parathyroid adenomas,[52] and parotid gland tumors[44,53] have been reported in patients with BHD, although it is unclear if these manifestations are truly related to BHD or represent incidental findings. There is debate regarding the association between BHD and colon neoplasms, with some studies suggesting no increased risk[48] while others suggest an increased risk in patients with certain genotypes.[54]

Radiology

Plain chest radiographs in BHD are generally unremarkable, and high-resolution computed tomography (HRCT) is needed to characterize the cystic change in detail. The pulmonary cysts in BHD have distinct features: the cysts tend to be lower lobe predominant, vary in size from a few millimeters to a few centimeters, are elliptical/lentiform in shape as opposed to the round/spherical cysts in other DCLDs, can have internal structures and septations, and generally occupy less than 10% of the pulmonary parenchyma (Fig. 61-2B).[47,55,56] Cysts in BHD have a predilection to abut the pleural surfaces and indent the mediastinal fat as well as encircle the bronchovascular structures in the so called air-cuff sign (Fig. 61-2C). The intervening pulmonary parenchyma appears grossly normal on HRCT. An expert radiologist can confidently distinguish BHD from other DCLDs in >90% of the cases based on HRCT features alone.[57] Renal tumors in BHD tend to be bilateral and multifocal and are often detected on CT or magnetic resonance imaging (MRI) of the abdomen.

Pathology

Fibrofolliculomas are characterized by cords and strands of epithelial cells that are two to four cells thick, radiating from a central aberrant hair follicle and surrounded by a well-circumscribed proliferation of loose connective tissue.[40] The histopathologic features of pulmonary cysts in BHD mimic the radiologic findings consisting of lower lobe–predominant cystic change that is typically subpleural or abutting the interlobular septa. The cysts can have internal septations, and the cyst walls are characteristically composed of a thin lining of pneumocytes with the surrounding normal lung parenchyma having no significant inflammation or fibrosis (Fig. 61-2D).[35] The cysts in BHD can be easily missed without integration of the clinical and radiographic history and lack specific histopathologic features to make a diagnosis based upon histopathology alone. Renal tumors in BHD can have varying histopathologic patterns, with the most common being hybrid oncocytic and chromophobe tumors (50%), followed by chromophobe (34%), clear cell (9%), oncocytoma (5%), papillary (2%), and other subtypes.[58]

Diagnosis

The diagnosis of BHD should be considered in all patients presenting with a spontaneous pneumothorax or incidentally detected cystic lung disease, but especially in young, nonsmoking patients. Careful attention must be given to personal or family history of skin lesions, pneumothoraces, or renal tumors. It is important to note, however, that there is wide phenotypic variability in BHD and the absence of family history or other organ involvement does not exclude the possibility of BHD. Another scenario that should warrant consideration of BHD is patients presenting with multiple/bilateral renal tumors—especially patients younger than 50 years.

More than one set of diagnostic criteria for BHD has been previously proposed.[16,39,59] In a patient with characteristic cystic change of BHD on chest CT scan and skin lesions on physical examination, confirmation of the presence of fibrofolliculomas by skin biopsy can be sufficient to confirm the diagnosis of BHD.[59] Genetic testing and the detection of pathogenic *FLCN* mutation is the most definitive way to establish the diagnosis of BHD. The sensitivity of genetic testing for BHD with the currently available detection methods is approximately 90%.[16]

Management

Management of the cutaneous and pulmonary manifestations of the disorder are briefly discussed below.

Cutaneous The skin lesions in BHD are benign, do not produce symptoms such as pain or pruritis, and as such do not warrant specific treatment. However, fibrofolliculomas can be cosmetically troubling to some patients with more prominent or disfiguring lesions, thus prompting patients to seek options for treatment. Hyfrecation, followed by curettage if necessary, has been successfully employed to treat BHD-associated fibrofollicuolmas.[60] Laser ablation is another option; however, this approach is somewhat limited by the risk of relapse.[40]

Pulmonary Performance of a baseline chest CT scan in all patients with BHD is suggested to determine the extent of cystic change. Patients should be reassured that the cysts in BHD generally occupy a small portion of the lung parenchyma, do not cause physiologic limitations, and tend not to progress over time.[43,47]

The management of BHD from a pulmonary perspective is largely focused on the treatment and prevention of spontaneous pneumothoraces. Patients should be educated about the presenting signs and symptoms of a spontaneous pneumothorax and advised to seek immediate medical attention in the event of these symptoms. There is an extremely high risk of recurrence (>70%) following conservative management of a spontaneous pneumothorax in patients with BHD.[41,42] Pleurodesis can reduce the risk of recurrence by one-half and is thus recommended following the initial episode of spontaneous pneumothorax rather than waiting for a recurrent episode, as typically occurs after a primary spontaneous pneumothorax.[42,61]

The risk of a spontaneous pneumothorax associated with atmospheric pressure changes as might be experienced with air travel has been estimated to be less than 1 event per 100 flights.[42,62] As such, air travel is considered safe for the majority of patients with BHD. Although a small survey-based study has demonstrated similar risk of development of spontaneous pneumothorax with deep sea diving,[62] we counsel patients to avoid underwater diving in accordance with the British Thoracic Society recommendations.[63]

Renal Renal cancer is the most serious complication of BHD. Serial screening for renal tumors should be performed in all BHD patients starting at the age of 20 years. Gadolinium-enhanced MRI may be the best long-term modality for renal tumor screening, as it provides superior sensitivity to renal ultrasound in its ability to detect small lesions and offers an ionizing radiation–free way to scan as opposed to CT scan. In patients without a detectable lesion, repeat imaging every 3 years or so is adequate. The risk of metastasis increases after a lesion has reached a size of 3 cm, and nephron-sparing surgery is recommended for renal tumors greater than or equal to 3 cm in size.[16,64]

Genetic Testing of Relatives Family members of affected individuals with BHD, especially first-degree relatives, are at an increased risk of inheriting the disease-causing mutation. Genetic counseling and consideration of screening for mutation detection should be offered to all at-risk adult relatives of patients with BHD.[59] Individuals with identified pathogenic *FLCN* mutation should be periodically screened for renal tumors similar to other patients with BHD.

■ Other Genetic DCLDs

A variety of genetic disorders such as Marfan syndrome,[65] Ehlers Danlos syndrome (type IV),[66] neurofibromatosis,[67,68] Cowden syndrome,[69] Proteus syndrome,[70] Coatomer subunit alpha (COPA) syndrome,[71] and Down syndrome[72] (Fig. 61-3A) can be associated with pulmonary cysts in a small proportion of patients (Table 61-3).

COPA syndrome is a recently described autosomal dominant disease that is caused by mutations in the *COPA* gene located on chromosome 1 resulting in impaired cellular vesicular transport function.[73] The hallmark of COPA syndrome is marked immune dysregulation, with a variety of autoantibodies having been detected in these patients. Clinically, the most commonly affected organs are lungs, kidneys, and joints. The manifestations begin early in childhood, and a majority of the patients are symptomatic prior to the age of 5 years.[73] Pulmonary involvement is almost universal in COPA syndrome, and cystic lung disease has been described in greater than 80% of the patients. Other pulmonary manifestations of COPA syndrome include hemoptysis, diffuse alveolar hemorrhage,

TABLE 61-3 Genetic Syndromes Associated with Pulmonary Cysts

Disease	Associated Genes	Category	Pulmonary Features	Other Clinical Features
Syndromes associated with tumors				
Tuberous sclerosis complex[75]	*TSC1*, *TSC2*	AD	Pulmonary cysts (LAM) in 30%–40% in females and 10%–15% in males, MMPH, pleural effusions	Skin lesions, seizures, developmental delays, tumors in various organs
Birt-Hogg-Dubé syndrome[47,55]	*FLCN*	AD	Pulmonary cysts in >80%	Cutaneous fibrofolliculomas, renal cysts, and renal cancers
Neurofibromatosis[67,68]	*NF1*, *NF2*	AD	Emphysema (25%), cysts (25%), ground-glass abnormality (37%), bullae (50%), and reticular abnormalities (50%)	Skin lesions, hamartomas, optic gliomas, and neurofibromas
Cowden syndrome[69]	*PTEN*	AD	Cysts in 80%, nodules	Mucocutaneous and visceral hamartomas and an increased lifetime risk of thyroid, breast, endometrial, renal, and colon cancers
DICER1 syndrome[77,81]	*DICER1*	AD	Pleuropulmonary blastoma (PPB), pulmonary cysts	Thyroid gland neoplasia, ovarian tumors, cystic nephroma, and tumors at various sites
Syndromes of disordered connective tissue				
Marfan syndrome[65]	*FBN1*	AD	10% have apical blebs and bullae	Tall stature, joint laxity, aortic dilation, arachnodactyly, pectus excavatum, and ocular findings
Vascular Ehlers-Danlos syndrome (type IV)[66]	*COL3A1*	AD	Pulmonary blebs, cystic lesions, and hemorrhagic or fibrous nodules	Easy bruising, thin and translucent skin, and tissue fragility
Cutis laxa[73]	*FBLN5*, *FBLN4*, *EFEMP2*, *LTBP4*, *ELN*	AD/AR	Emphysema, bronchiectasis	Loose, saggy, inelastic skin, hernias, visceral diverticula, joint hypermobility
FLNA mutation[74]	*FLNA*	XL	Cysts, emphysema	Intellectual disability, seizures, and cardiac valvular anomalies
Others				
Down syndrome[73]	—	Chromosomal, trisomy 21	Cysts in 20%–36%; usually subpleural, sleep apnea	Dysmorphic features, developmental delay, congenital malformations
Proteus syndrome[70]	*AKT1*	Somatic mosaic mutation	Cysts in ~10%	Asymmetric growth, nevi, vascular malformations
COPA syndrome[71]	*COPA*	AD	Pulmonary cysts (80%), diffuse alveolar hemorrhage, and follicular bronchiolitis	Arthritis, proteinuria, nephropathy, autoantibodies
"Brain-thyroid-lung" syndrome[77,78]	*NKX2-1*	AD	Cysts, alveolar proteinosis, interstitial pneumonitis	Chorea, other neurologic symptoms, hypothyroidism

AD, autosomal dominant; AR, autosomal recessive; LAM, lymphangioleiomyomatosis; MMPH, multifocal micronodular pneumocyte hyperplasia; XL, X linked.

and ILD, most commonly in the form of follicular bronchiolitis/lymphoid interstitial pneumonia.[71]

Other genetic syndromes such as cystic fibrosis, α1-antitrypsin deficiency, cutis laxa,[74] and filamin A *(FLNA)* mutation[75] (Fig. 61-3B) also cause lung destruction but manifest mainly as emphysema, bronchiectasis, and alveolar growth abnormalities rather than true pulmonary cysts. More common DCLDs such as LAM and PLCH also have a genetic basis but are better classified under the neoplastic subcategory.[1,76]

■ Developmental DCLDs

Bronchopulmonary dysplasia (BPD) and congenital pulmonary airway malformation (CPAM) are the most common developmental abnormalities that can present as DCLD. These disorders are typically identified in the pediatric age groups, although rarely the presentation may be delayed until adulthood.[77] CPAM is the most common lower respiratory tract malformation and is believed to arise due to in utero obstruction during lung development (Fig. 61-3C). CPAM is further classified based on the cyst size, which can vary from a few millimeters to more than 2 cm.[78] BPD is a chronic lung disease caused by disruption in normal alveolar growth due to premature birth and is believed to result from an aberrant reparative response to both antenatal injury and repetitive postnatal injury to the developing lungs (Fig. 61-3D).[79] Radiologically, BPD manifests as alveolar simplification that can mimic DCLDs.[80] Other congenital disorders that can produce pulmonary cystic change include congenital lobar emphysema, pleuropulmonary blastoma (PPB) due to *DICER1* mutations (discussed under neoplastic etiologies),[81] and brain-thyroid-lung syndrome caused by *NKX2-1* mutations.[78,82]

DIFFUSE CYSTIC LUNG DISEASES CAUSED BY LYMPHOPROLIFERATIVE DISORDERS

Diffuse cystic lung disease may be associated with lymphoproliferative disorders. Below we consider cystic lung disease seen with

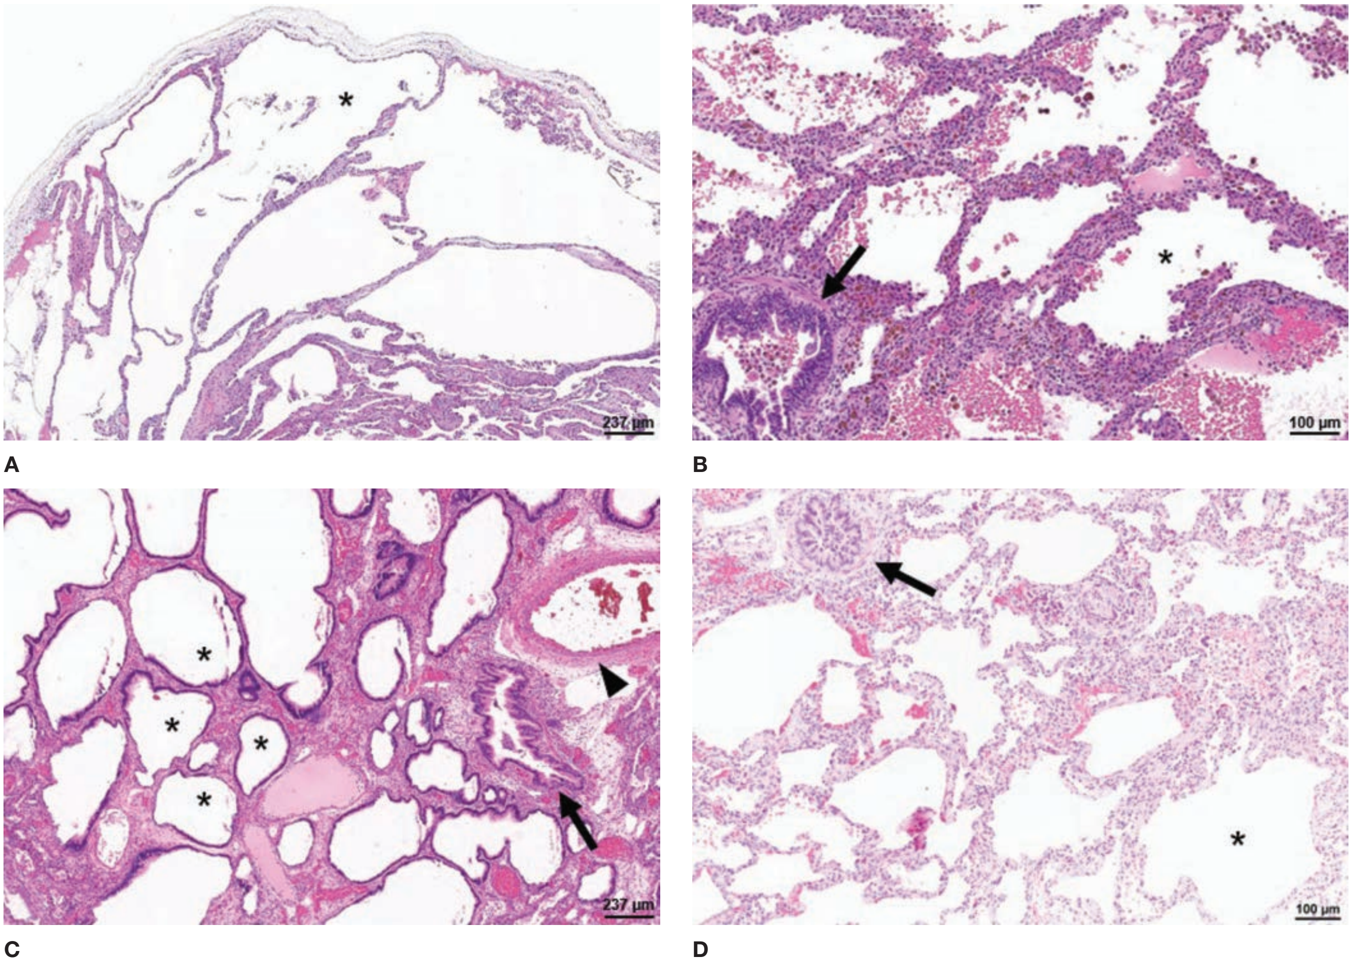

Figure 61-3 Histopathology of pulmonary abnormalities in multiple genetic and developmental diffuse lung diseases that can present as pulmonary cysts. **A.** Lung growth abnormality in a patient with trisomy 21 with cystic enlargement of subpleural alveoli *(*)* as a result of deficient alveolarization. **B.** Lung explant from a patient with a pathogenic filamin A mutation showing marked alveolar enlargement and simplification *(*)* reflective of a lung growth abnormality. The marked alveolar enlargement can be appreciated by comparing the alveoli to the bronchiole *(arrow)*, which is normally larger in size. **C.** Congenital pulmonary airway malformation (CPAM) characterized by abnormally opposed bronchiole-like structures *(*)* that unlike the normal bronchiole *(arrow)* are not accompanied by arteries *(arrowhead)*. **D.** Bronchopulmonary dysplasia manifested as chronic neonatal lung disease with prominent distension and simplification of alveoli *(*)*, which are larger than the bronchiole *(arrow)*.

follicular bronchiolitis and lymphoid interstitial pneumonia, amyloidosis, and light chain deposition disease.

■ Follicular Bronchiolitis/Lymphoid Interstitial Pneumonia

Follicular bronchiolitis (FB) and lymphoid interstitial pneumonia (LIP) are clinicopathologic terms describing two entities along a continuum. These entities are characterized by polyclonal proliferations and infiltration of lymphocytes, varying from involvement of the conducting airways to more diffuse lung involvement with cellular expansion of the pulmonary interstitium including the alveolar septa.[77] The lymphoid follicular hyperplasia is centered around the airways in FB, whereas LIP represents diffuse involvement of the pulmonary parenchyma by the reactive lymphoid cells.[83]

Pathogenesis

Although FB/LIP can occasionally occur in isolation in an idiopathic fashion, these entities are typically seen in association with underlying immune dysregulatory disorders. The most common conditions that predispose to the development of FB/LIP include autoimmune conditions such as Sjögren syndrome, systemic lupus erythematosus, and rheumatoid arthritis, as well as other immune-dysregulatory states such as common variable immune deficiency (CVID) and, principally in the pediatric population, human immunodeficiency virus (HIV) infection. These associations suggest that FB/LIP develops as a result of aberrant inflammatory responses to chronic antigenic stimulation in hosts with underlying immune-dysregulatory conditions. The exact mechanism that drives the formation of pulmonary cysts in FB/LIP is not fully understood. Proposed hypotheses include a check-valve mechanism allowing air entry but not egress due to bronchiolar compression by the reactive lymphoid tissue or ischemic parenchymal destruction due to vascular obstruction.[77]

Clinical Manifestations

The pulmonary symptoms related to FB/LIP are relatively nonspecific and most commonly consist of dyspnea on exertion and chronic cough.[84] Spontaneous pneumothorax can occur in patients with cystic FB/LIP and may be the presenting manifestation that leads to the diagnosis. However, for reasons that are not entirely clear, the incidence of spontaneous pneumothorax appears to be lower in patients with FB/LIP compared to patients with other DCLDs such as BHD and LAM.[61]

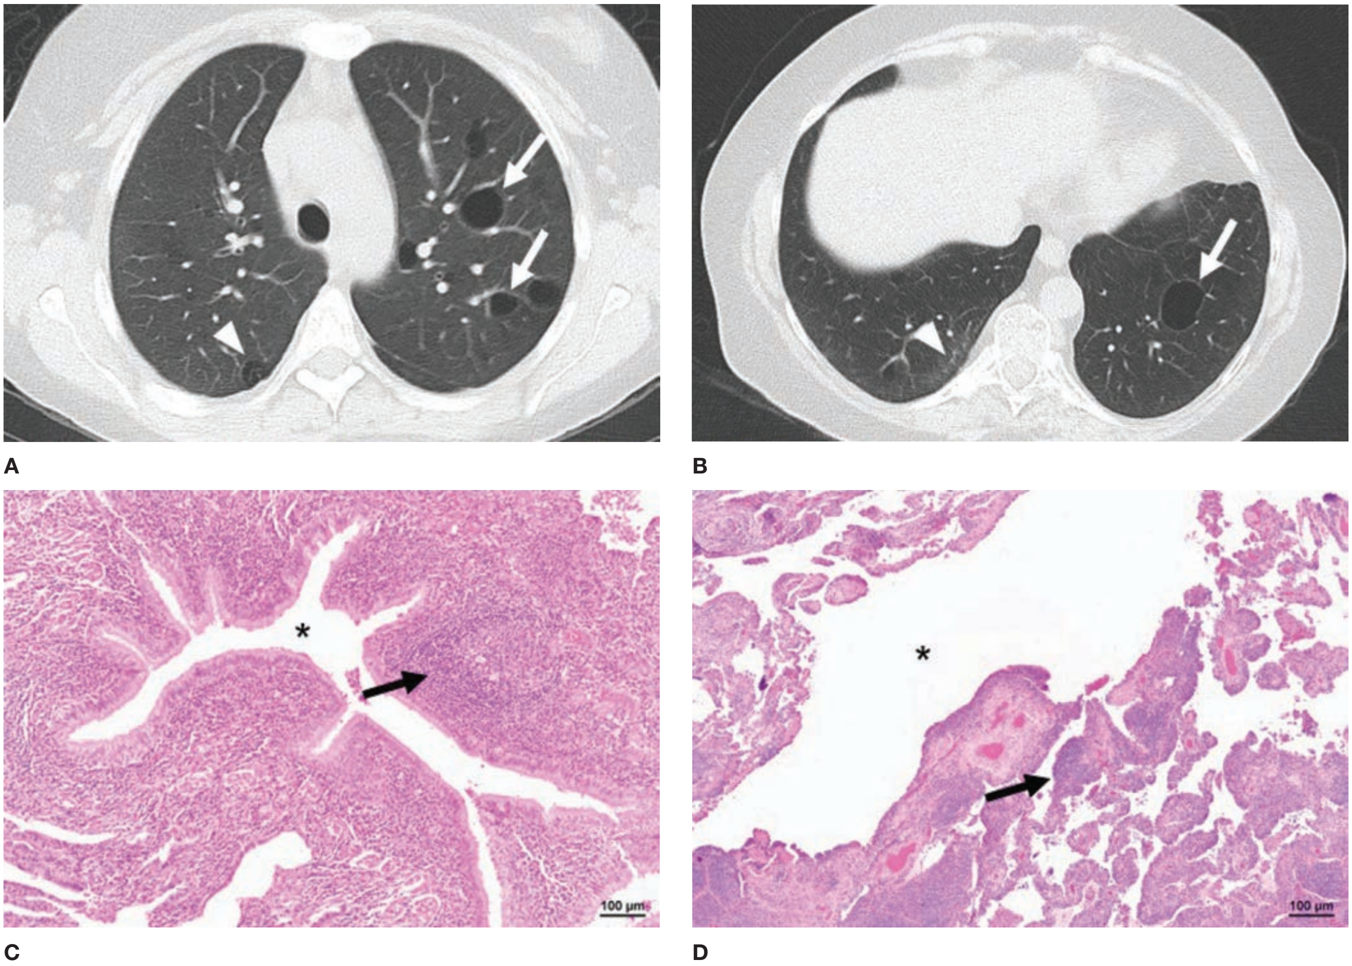

Figure 61-4 Radiologic and histopathologic manifestations in follicular bronchiolitis (FB) and lymphoid interstitial pneumonia (LIP). **A.** Multiple thin-walled cysts, some of which are bordered by eccentric vessels *(arrows)* and some with internal septations *(arrowhead)* are present in an axial CT image of a patient diagnosed with overlapping FB/LIP. **B.** Cysts *(arrow)* and areas of peripheral ground glass opacification and reticulations *(arrowhead)* are present in an axial CT image from a separate patient diagnosed with Sjögren syndrome. **C.** Histologic image of a bronchiole with features of FB with marked compression of the bronchiolar lumen *(*)* by a dense peribronchiolar chronic inflammatory infiltrate including a lymphoid follicle with a prominent germinal center *(arrow)*. **D.** The lung parenchyma in this same lung biopsy also had cystic spaces *(*)* and diffuse alveolar septal widening by a dense cellular infiltrate *(arrow)* leading to the diagnosis of LIP.

Radiology

Cystic change is frequently associated with other findings on HRCT in FB/LIP. For instance, bronchiolocentric micronodules are commonly seen in patients with FB. In addition to nodules, patients with LIP can have ground glass opacities and reticular changes on HRCT. Pulmonary cysts can be seen in greater than two-thirds of patients with FB/LIP[85,86] and often have distinct radiologic features that can help distinguish them from cysts seen in other DCLDs.[57] The cysts in FB/LIP tend to be lower lobe predominant, vary in size from a few millimeters to up to 5 to 7 centimeters, are often bordered by eccentric vessels, and frequently have internal septations and structures (Fig. 61-4A and B).[87]

Pathology

FB is characterized by a dense peribronchiolar chronic inflammatory infiltrate with prominent lymphoid follicles with reactive germinal centers sparing the intervening lung parenchyma (Fig. 61-4C). In contrast, LIP is characterized by diffuse interstitial involvement by a similar dense chronic inflammatory infiltrate leading to marked widening of the alveolar septa with compression and distortion of the alveolar spaces (Fig. 61-4D). Proteinaceous material is also often present within alveolar spaces in LIP but is not seen in FB. Fibrosis, if present, is minimal. Cases with overlapping features of FB and LIP exist, thus leading to the notion that these two entities represent a disease continuum with FB considered to be an earlier stage of disease. The inflammatory infiltrate in both FB and LIP consists mainly of small lymphocytes admixed with variable numbers of plasma cells. The lymphocytic infiltrate is composed of a mixture of B and T cells, with the B cells often localized to nodular lymphoid follicles and the prominent interstitial infiltrate in LIP composed predominantly of T cells with only scattered B cells.[77,83,88] Histiocytes and loose granulomas can be present in LIP and may be more prominent in patients with immunodeficiency, particularly CVID. Nodular lymphoid aggregates with reactive germinal centers are present in up to half of the patients with idiopathic and connective tissue disease–associated forms of LIP but are less common in patients with HIV.

Diagnosis

Confirmation of FB/LIP requires histopathologic evaluation of a lung biopsy. The yield of transbronchial biopsy is low; therefore surgical lung biopsy is the procedure of choice.[84] However, the presence of common coexisting conditions such as autoimmune or other immune-dysregulatory states in patients with characteristic cystic change of FB/LIP is often sufficient to establish a clinical diagnosis of FB/LIP and obviates the need for invasive biopsy procedures.[87]

Management

While corticosteroids and other immunosuppressive drugs have been successfully used to treat the infiltrative parenchymal manifestations of FB/LIP, the role of treatment in preventing progression of DCLD remains unknown.[84,89] In our experience, for the vast majority of patients with cystic FB/LIP, conservative management with serial physiologic and radiologic monitoring seems sufficient. FB/LIP associated with HIV can improve with antiretroviral treatment.[90] Patients with CVID and hypogammaglobulinemia may need intravenous immune globulin replacement to prevent recurrent infections.[91]

Although low, there is a risk of transformation to mucosa-associated lymphoid tissue (MALT) lymphoma in patients with FB/LIP.[84,88] Close follow-up with periodic chest imaging every 2 to 3 years may be helpful to monitor this risk. Clinicians should consider biopsy of suspicious ground glass or consolidative nodules to rule out lymphoma if there is evidence of growth on serial imaging.[77]

■ Amyloidosis

Amyloidosis consists of a heterogenous group of diseases characterized by the extracellular deposition of insoluble peptides and precursor proteins in an abnormal fibrillary fashion. These abnormal proteins are arranged in β-pleated structures instead of the normal α-helical forms.[77,92]

Multiple subtypes of amyloidosis are now recognized based upon the underlying precursor protein and the affected organs. Pulmonary involvement from amyloidosis can occur as part of systemic disease or as a localized disease. Localized pulmonary amyloidosis can manifest as multiple pulmonary nodules, pulmonary cysts, and tracheobronchial lesions with the nodular form being the most common subtype. Pulmonary nodules in amyloidosis tend to be multiple and bilateral with varying nodule size.[93]

Cystic change is an uncommon presentation of pulmonary amyloidosis and can be seen either in isolation or in the presence of a coexisting connective tissue disease, most commonly Sjögren syndrome.[93,94] The cysts in amyloidosis are thin walled and present bilaterally, either as diffuse cysts or in a lower lobe–predominant distribution (Fig. 61-5A and B). The size of the cysts tends to be variable with small (<1 cm) as well as large cysts (>4 cm) described in these patients. Some cysts are lobulated with internal structures and septations. Peribronchovascular and subpleural cyst distributions are common in amyloidosis. Most patients with amyloid-associated cystic change also have coexisting pulmonary nodules. In approximately one-third of cases, amyloidosis may be associated with underlying MALT lymphoma.[93,94]

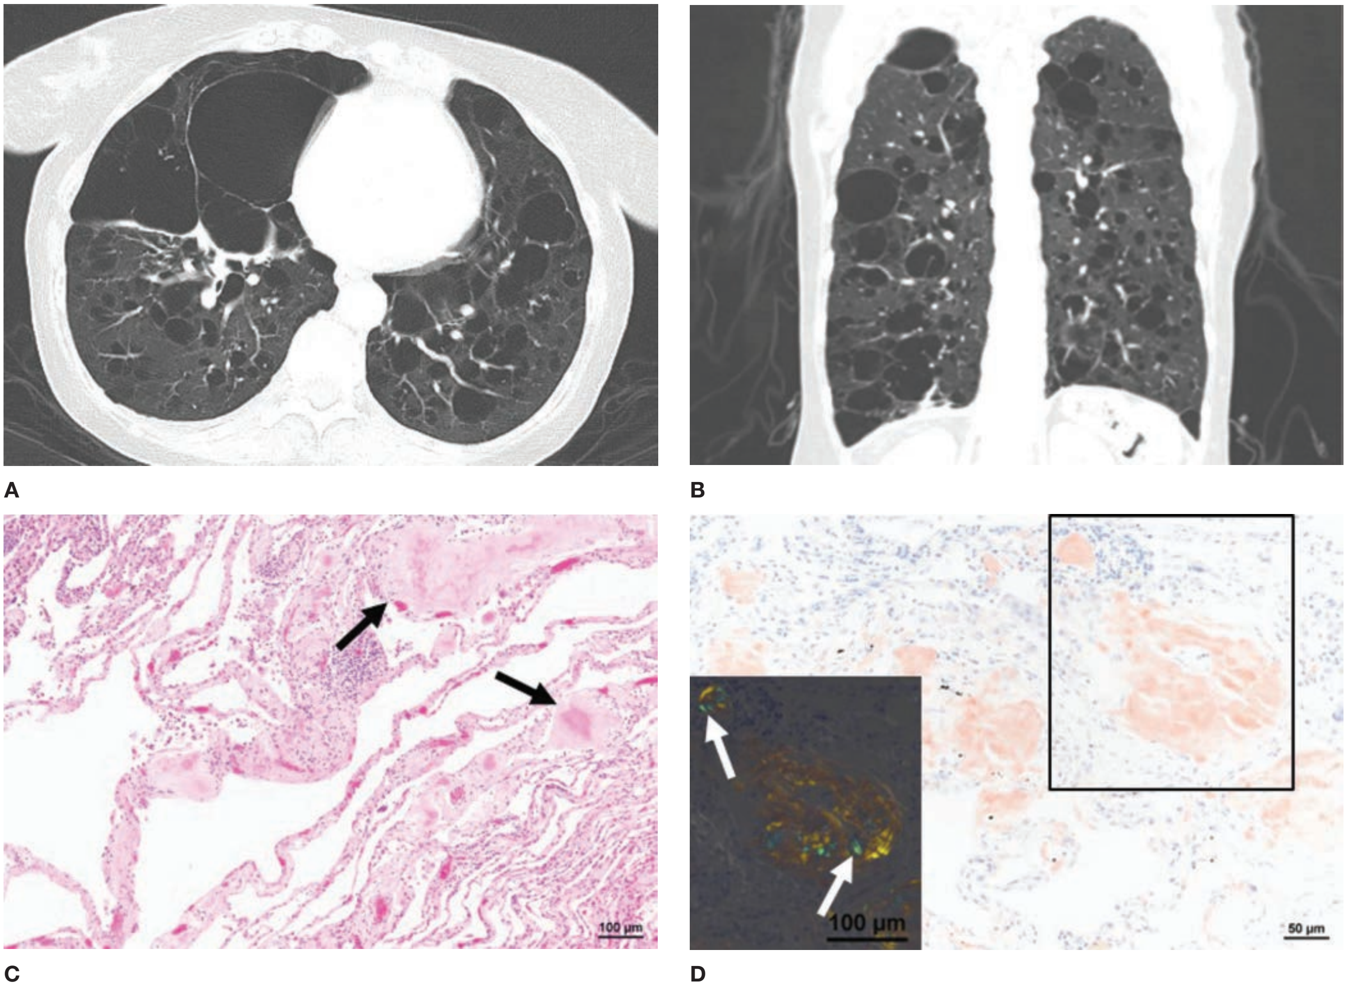

Figure 61-5 Radiologic and histopathologic manifestations in amyloidosis. **A,B.** Chest CT images of a patient with amyloid showing innumerable cysts of variable size in a diffuse craniocaudal distribution. **C.** Histologic image from a man undergoing lung biopsy for diagnosis of a suspected interstitial lung disease showing deposition of amorphous, eosinophilic material within the alveolar septa *(arrows)*. **D.** Congo red stain of the same biopsy showing the typical orange-red staining of amyloid under routine brightfield light microscopy with examination under polarized light demonstrating the characteristic birefringence reflected in the apple-green color *(arrows in inset that represents boxed area)*.

Proposed mechanisms for the formation of pulmonary cysts in amyloidosis include a ball-valve effect due to amyloid deposition around the bronchiolar walls leading to overexpansion of distal air spaces,[95] and destruction of alveolar walls either due to the action of matrix degrading enzymes or due to ischemia resulting from amyloid deposition around the alveolar capillaries.[96]

Establishing a diagnosis of amyloidosis as the cause for DCLD requires histopathologic confirmation. Diagnostic histopathologic findings in amyloidosis include demonstration of amorphous, eosinophilic amyloid deposits that exhibit apple-green birefringence in Congo red–stained sections viewed by polarizing microscopy **(Fig. 61-5C and D)**. Electron microscopy shows a typical mesh of nonbranching fibrils that are 7.5 to 12.0 nm in diameter and arrayed in a disorderly fashion. Immunoglobulin light-chain protein deposition can also be identified by immunohistochemistry.[77]

The natural history of cystic lung disease due to amyloidosis is not well understood, with single-center data suggesting progressive worsening over time in greater than two-thirds of patients.[93] Treatment of amyloidosis is based upon identification of the pathogenic protein subtype and the extent of disease involvement (localized versus systemic). While isolated pulmonary amyloidosis generally tends to have a good prognosis and may be amenable to conservative management, systemic amyloidosis almost always requires consultation with an expert hematologist and consideration of chemotherapeutic regimens or stem cell transplantation.[92]

■ Light Chain Deposition Disease

Light chain deposition disease (LCDD), first described in 1976, belongs in the family of monoclonal immunoglobulin deposition diseases and is most commonly characterized by the abnormal tissue accumulation of monotypic kappa light chains.[77,97] LCDD is often seen in association with other lymphoproliferative disorders such as multiple myeloma and monoclonal gammopathy of unknown significance (MGUS).[98] It generally represents a multisystemic disorder, with progressive renal involvement being a consistent feature.[99]

In contrast to systemic LCDD, pulmonary LCDD may be limited to the lungs and can have nodular and/or cystic forms. Pulmonary involvement by LCDD more commonly manifests as multiple, bilateral nodules; however, cystic forms mimicking other more common DCLDs such as LAM and PLCH also have been described.[100–102] Sjögren syndrome can predispose to the development of amyloidosis as well as LCDD.[87,102–104] The cysts in LCDD are multiple, thin-walled, variable in size from less than 2 cm to more than 4 cm, and present bilaterally in a lower lung zone or diffuse distribution.[100–102] Although not completely understood, elastolysis secondary to increased matrix metalloproteinase activity has been proposed as a causative mechanism for cyst formation in LCDD.[105]

Serum or urine protein electrophoresis lack the sensitivity to properly screen for the presence of underlying LCDD. An abnormal serum free light chain ratio is seen in more than two-thirds of patients with LCDD and may be more helpful as a screening test.[106] Definitive diagnosis of LCDD requires histopathologic confirmation. The characteristic histopathologic findings in LCDD include the irregular deposition of nonfibrillary acellular eosinophilic material, most commonly monotypic kappa light chains, in the walls of alveoli, small airways, and vessels. Surrounding foreign-body giant cell reaction is common. The amorphous depositions in LCDD lack the ß-pleated configuration typically seen in amyloidosis and as such do not bind to Congo red or exhibit apple-green birefringence under polarized microscopy.[77,101] Immunoglobulin light chains can also be isolated by mass spectrometry,[107] especially in those unusual cases where the diagnosis remains uncertain following expert histopathologic review.

The natural history of disease progression in LCDD is not well established, although some cases of progressive decline in lung function resulting in respiratory failure have been described.[108] No specific disease-modifying treatments exist for pulmonary LCDD. Hematopoietic stem cell transplantation was reported to stabilize lung function in a patient with pulmonary cystic LCDD associated with an extrapulmonary lymphoma.[109] Lung transplantation is an option for patients with severe pulmonary involvement.[108]

NEOPLASTIC DIFFUSE CYSTIC LUNG DISEASES

A variety of neoplastic disorders can present as DCLD **(Table 61-2)**. In fact, two of the most common DCLDs encountered in clinical practice, LAM and PLCH, represent low-grade neoplasms driven by abnormal signaling of the mechanistic target of rapamycin (mTOR) and the mitogen-activated protein kinase (MAPK) pathway, respectively.[110,111] Please refer to Chapters 59 and 60 for further in-depth review of PLCH and LAM, respectively.

Among high-grade neoplasms, cystic lung disease can be seen in both primary lung cancers as well as metastatic disease. Typically, these lesions begin as nodular opacities that subsequently cavitate to form cysts. Non–small-cell lung carcinoma (NSCLC) rarely can produce pulmonary cysts, with adenocarcinomas being the most common cause of cystic NSCLC followed by squamous cell carcinomas **(Fig. 61-6A)**.[112] The cystic change from primary lung cancers consists of thick-walled cysts/cavities, is limited to only a few cysts, and is generally not confused with the prototypic DCLDs. On the other hand, metastatic malignancies, especially from abdominopelvic sources, can produce pulmonary cysts that are more numerous and can be mistaken for other more common DCLDs.[2] As a group, sarcomas represent the most common malignancy that can produce pulmonary cysts **(Fig. 61-6B)**. Cystic and/or cavitary changes have been described in ~25% of patients with metastatic sarcomas and are frequently complicated by spontaneous pneumothoraces and portend a poor prognosis.[113] Metastatic endometrial synovial sarcoma and synovial sarcomas can produce cysts that can look quite similar to more common DCLDs such as LAM **(Fig. 61-6C and D)**.[1,114]

Pleuropulmonary blastoma (PPB) is the most common primary pediatric pulmonary malignancy, typically identified early in childhood.[81] Heterozygous mutations in *DICER1* have been identified in >70% of the cases of PPB and have significantly enhanced our understanding of the development of PPB.[115] The current pathogenic model suggests *DICER1* mutations alter early lung development to drive PPB formation, with subsequent additional somatic mutations driving progression to sarcoma.[116] PPB is classified into three subtypes based on the morphologic and radiographic appearance: type I (purely cystic), type II (mixed cystic and solid), and type III (purely solid). These subtypes represent stages in tumor progression and can help predict overall outcomes, with estimated 5-year survival rates of 91%, 71%, and 53% in type I, II, and III PPBs, respectively.[81] Radiologically, cystic PPB can manifest as multilobulated cysts with grossly normal intervening pulmonary parenchyma. The major differential diagnosis for cystic PPB is CPAM, which can be clinically and radiographically indistinguishable. Genetic testing and serial imaging are needed to identify high-risk lesions at the earliest opportunity to ensure PPB is detected and treated at the early cystic type I stage, before progressing to high-grade sarcoma that is associated with a worse prognosis. Definitive PPB diagnosis requires histopathologic confirmation with demonstration of primitive mesenchymal cells in the cyst walls.[117]

INFECTIOUS DIFFUSE CYSTIC LUNG DISEASES

Pulmonary infections can occasionally present with cystic change on chest radiographs, most commonly in the form of pneumatoceles. The prototypic infection producing cystic lung disease

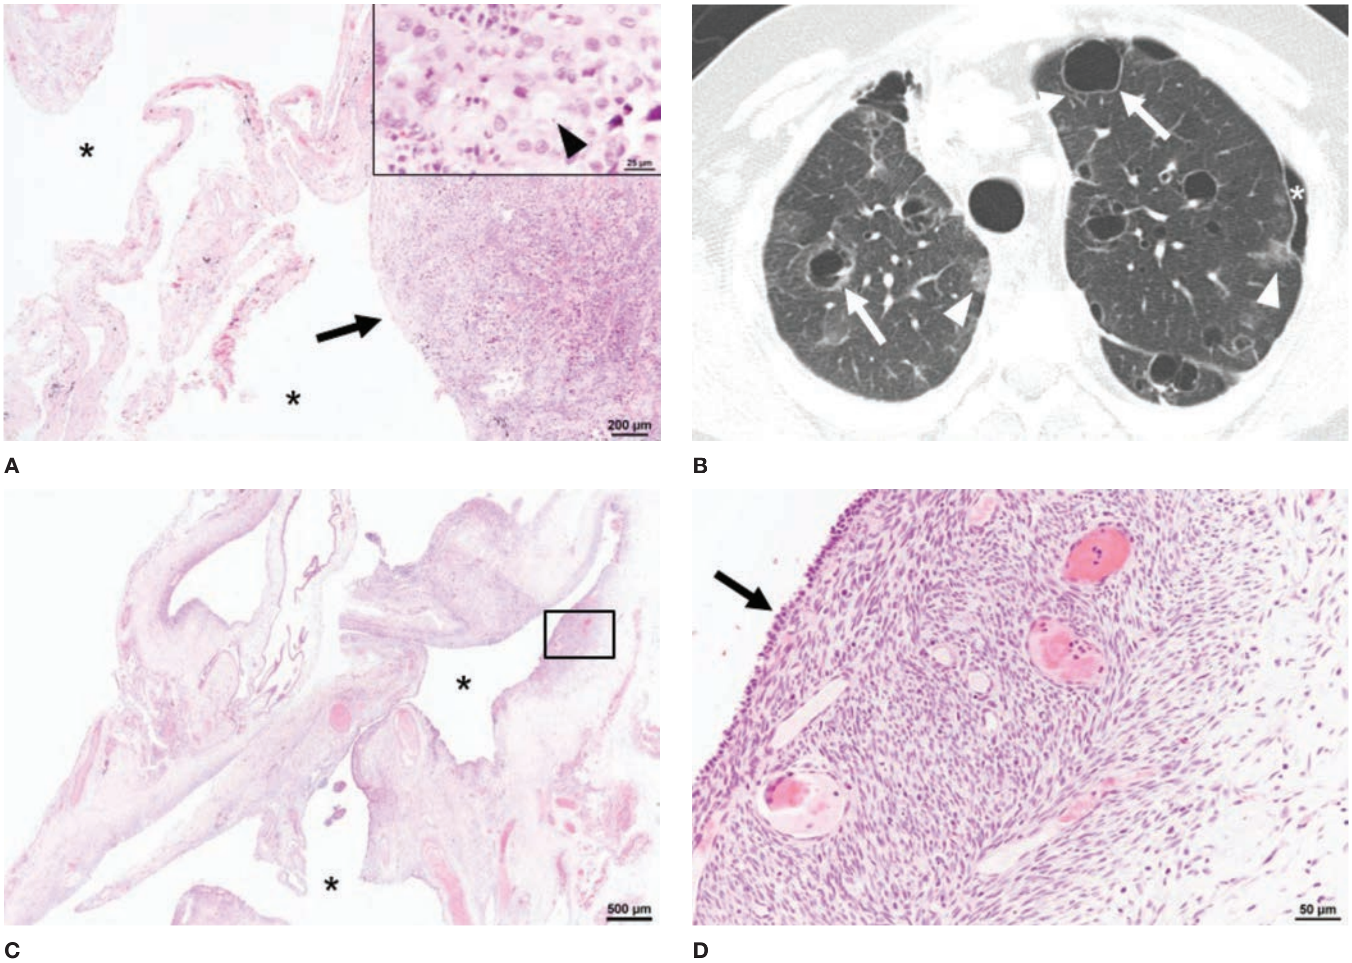

Figure 61-6 Radiologic and histopathologic manifestations in neoplastic diffuse cystic lung disease. **A.** Histologic image of a solid mass *(arrow)* adjacent to cystically dilated airspaces (*) representing bullous emphysema. Higher-magnification image *(inset)* confirmed the diagnosis of poorly differentiated non–small-cell lung carcinoma with glandular formation *(arrowhead)* indicating features of adenocarcinoma. **B.** Axial CT image of a patient with metastatic angiosarcoma showing multiple cysts *(arrows)*, areas of ground glass opacification *(arrowheads)*, and a small left pneumothorax *(*)*. **C.** Histologic image of a resected multicystic *(*)* lesion from an 18-year-old female with scattered more cellular areas noted in the cyst wall *(boxed area)*. **D.** Higher-magnification image of the boxed area in **C** showing a focus of relatively bland-appearing spindle cells immediately beneath the cuboidal epithelium lining the cystic space *(arrow)*. The suspected morphologic diagnosis of synovial sarcoma was further confirmed by molecular studies on the lung biopsy being positive for a t(X;18) translocation present in most synovial sarcomas with detection of a SS18 (*SYT*) gene rearrangement by fluorescence in situ hybridization (FISH).

is *Pneumocystis jirovecii* pneumonia (PJP). *Pneumocystis jirovecii* is a human-specific fungal pathogen that typically causes opportunistic infections in immunocompromised hosts, particularly patients with impaired cell-mediated immunity such as underlying HIV infection. The typical clinical presentation of PJP in patients with HIV is characterized by subacute onset of dyspnea, fever, and nonproductive cough; presentation is often more acute in non-HIV immunocompromised patients.[118] PJP usually manifests as bilateral, diffuse, perihilar ground glass attenuation and reticulation; however, a minority of cases (10%–34%) can present with a predominant DCLD pattern.[1,118,119] Cysts associated with PJP are usually numerous, bilateral, diffusely distributed or upper lobe predominant, and of variable size and wall thickness (Fig. 61-7A and B).[118,119] Formation of pulmonary cysts is more commonly seen in PJP associated with HIV (~56%) compared with other immune-suppressed states (~3%).[120] Spontaneous pneumothorax can occur due to rupture of subpleural cysts and portends a poor prognosis.[118] Elevated serum β-D-glucan levels can be a useful screening test; however, elevated levels can be seen in other fungal infections and as such lack specificity.[121] Diagnostic confirmation requires identification of microorganisms with appropriate staining (Fig. 61-7C and D). The cysts can shrink or completely resolve with treatment of PJP.[119,122]

Recurrent respiratory papillomatosis (RRP), caused by human papillomavirus (HPV) infections, can rarely present with a DCLD pattern. RRP is primarily seen in childhood and, in most cases, is limited to larynx and upper tracheal involvement. Distal bronchopulmonary spread of RRP is uncommon and occurs in approximately 1% to 5% of cases.[123–126] The radiologic findings of pulmonary RRP are variable and include multiple nodules in varying stages of evolution, including some with cavitation and others with cyst formation.[1]

DIFFUSE CYSTIC LUNG DISEASES ASSOCIATED WITH INTERSTITIAL LUNG DISEASES

Cystic changes, although not a dominant feature, can often accompany other fibrotic interstitial lung diseases (ILDs) such as hypersensitivity pneumonitis (HP), desquamative interstitial pneumonia (DIP), and sarcoidosis.[1] DIP is an ILD strongly associated with exposure to cigarette smoke.[127] The most common radiologic

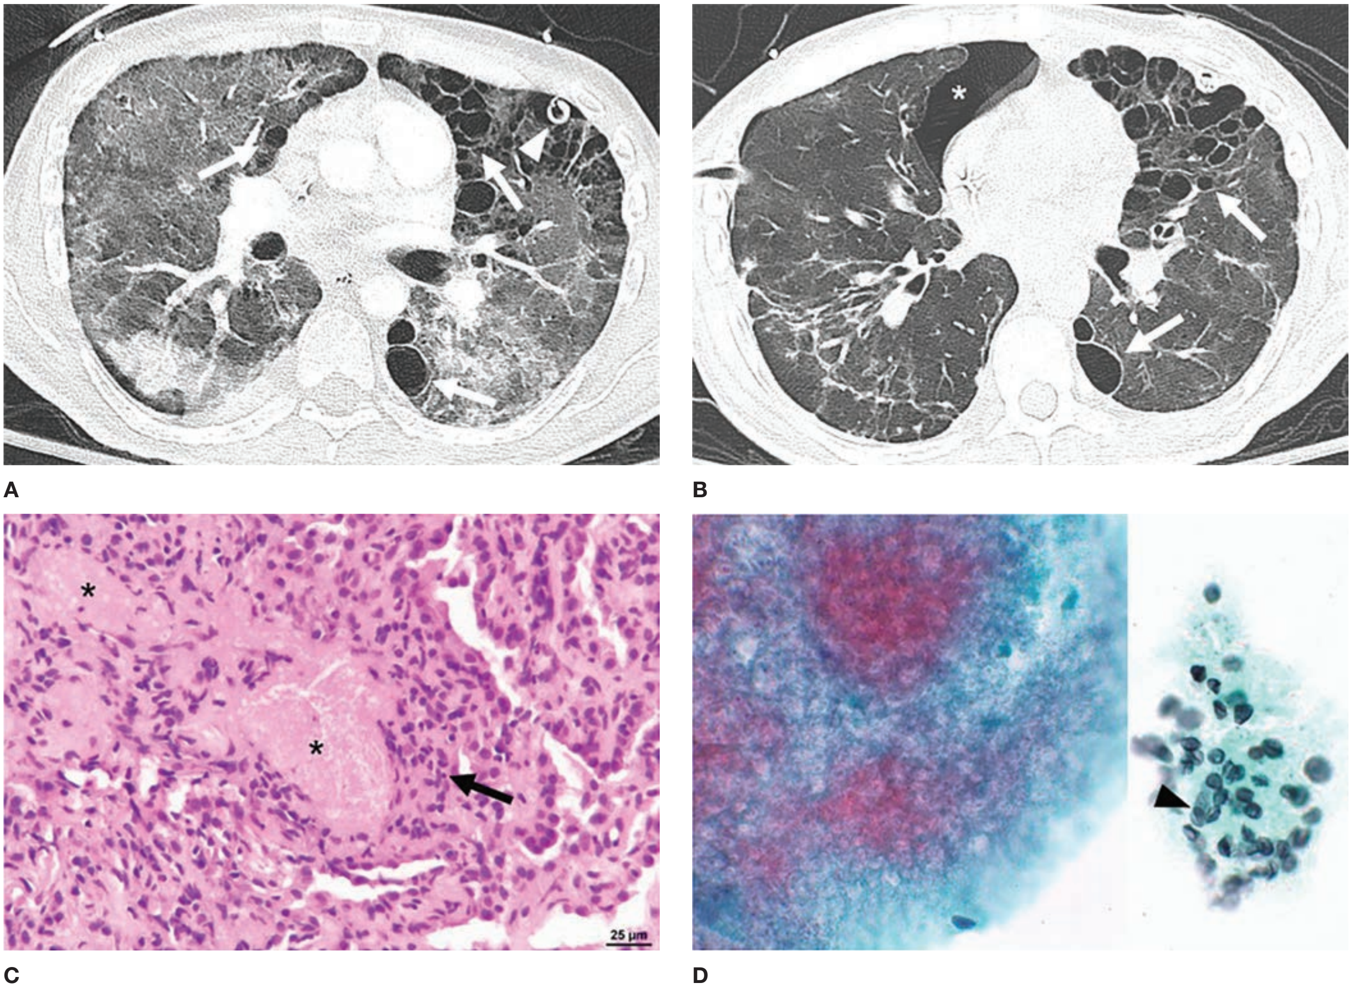

Figure 61-7 Radiologic and histopathologic manifestations in *Pneumocystis jirovecii* pneumonia (PJP). **A.** Axial chest CT image from an immunocompromised patient with acute PJP showing widespread areas of ground glass opacification with multiple cysts *(arrows)* and a left pneumothorax with a chest tube in place *(arrowhead)*. **B.** Images from a follow-up study as the patient was recovering shows better-defined cysts *(arrows)* with resolution of the ground glass opacifications and a right pneumothorax *(*)*. **C.** Histologic image of a biopsy from a patient with PJP pneumonia showing the classic frothy exudates within the alveolar spaces *(*)* with variable interstitial inflammation in the surrounding lung parenchyma *(arrow)*. **D.** The frothy exudates can also be seen in cytologic bronchoalveolar lavage preparations with diagnosis confirmed by identifying the microorganisms that appear as round, often indented or helmet-shaped, cyst forms *(arrowhead)* best highlighted with Gomori methenamine silver (GMS) stain.

abnormality in DIP is diffuse ground glass attenuation with cystic change variably reported in 30% to 75% of patients with DIP.[128,129] The cysts in DIP overlap with areas of ground glass attenuation, often involve a small percentage of the pulmonary parenchyma, and are more common in the lower lung zones (Fig. 61-8A and B).[129] The histologic hallmark of DIP is diffuse filling of the distal airspaces with abundant pigmented macrophages (Fig. 61-8C and D).

Cystic change in HP is primarily limited to areas of ground glass attenuation. It is almost always accompanied by other radiologic features of HP such as centrilobular nodules and mosaic attenuation indicative of air trapping (Fig. 61-9A and B).[130] The centrilobular nodules and ground glass attenuation seen in HP radiographically corresponds to patchy bronchiolocentric cellular chronic interstitial inflammatory infiltrates that extent into the surrounding alveolar septa (Fig. 61-9C). Loose non-necrotizing granulomas and organizing pneumonia also are frequently present (Fig. 61-9D). The cysts in sarcoidosis tend to be perihilar compared with the subpleural cysts in other fibrotic ILDs (Fig. 61-10A).[131,132] Sarcoidosis is classically manifested histologically as well-formed, non-necrotizing interstitial granulomas distributed in a lymphangitic pattern around the bronchovascular bundles and along the pleura and interlobular septa (Fig. 61-10B and C). Although associated with cystic change, the presence of other more typical radiologic findings generally makes it straightforward to distinguish these ILDs from the pure DCLDs.

SMOKING-RELATED DIFFUSE CYSTIC LUNG DISEASES

PLCH is the prototypic smoking-related DCLD (Chapter 59). DIP, discussed in the preceding section, can also produce pulmonary cysts. While PLCH and DIP are the most common smoking-related disorders that produce lung cysts, DCLD resulting from cigarette smoke exposure has been reported in the absence of these disorders and can resemble the more common DCLDs such as LAM. The mechanism of cyst formation in these cases is not well understood but is postulated to involve a ball-valve mechanism and distal hyperinflation due to small airway inflammation and mucostasis as a result of cigarette smoke exposure.[133] It is worth noting that small airway narrowing resulting in distal hyperinflation and cyst formation has also been described in other forms of bronchiolitis.[134–136]

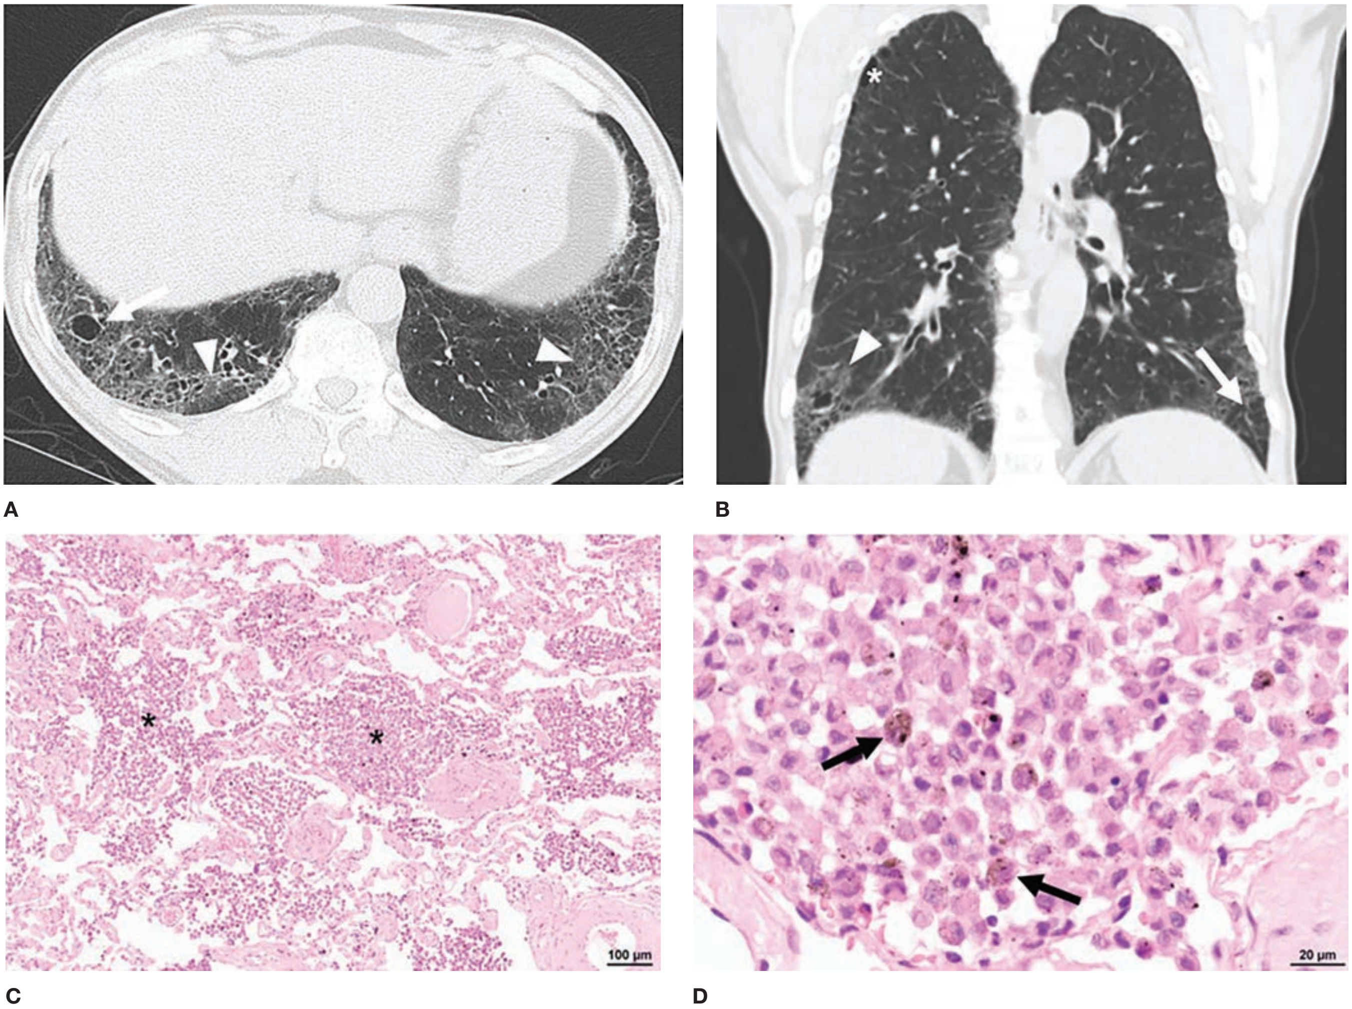

Figure 61-8 Radiologic and histopathologic manifestations in desquamative interstitial pneumonia (DIP). **A,B.** Axial (**A**) and coronal (**B**) images of a patient with DIP showing basal predominant cystic change *(arrows)* and ground glass opacification *(arrowheads)* with emphysema related to smoking in the upper lung zones *(*)*. **C.** Histologic image showing the hallmark of DIP, which is filling of distal airspaces with large numbers of pigmented macrophages *(*)*. Significant interstitial fibrosis is not a feature of DIP, and interstitial inflammation is usually absent. **D.** The cytoplasmic pigment in the macrophages is yellow-brown and variably sized with blurry borders *(arrows)*. This smoking-related pigment needs to be distinguished from hemosiderin pigment, which is typically larger and golden to dark brown with well-demarcated borders.

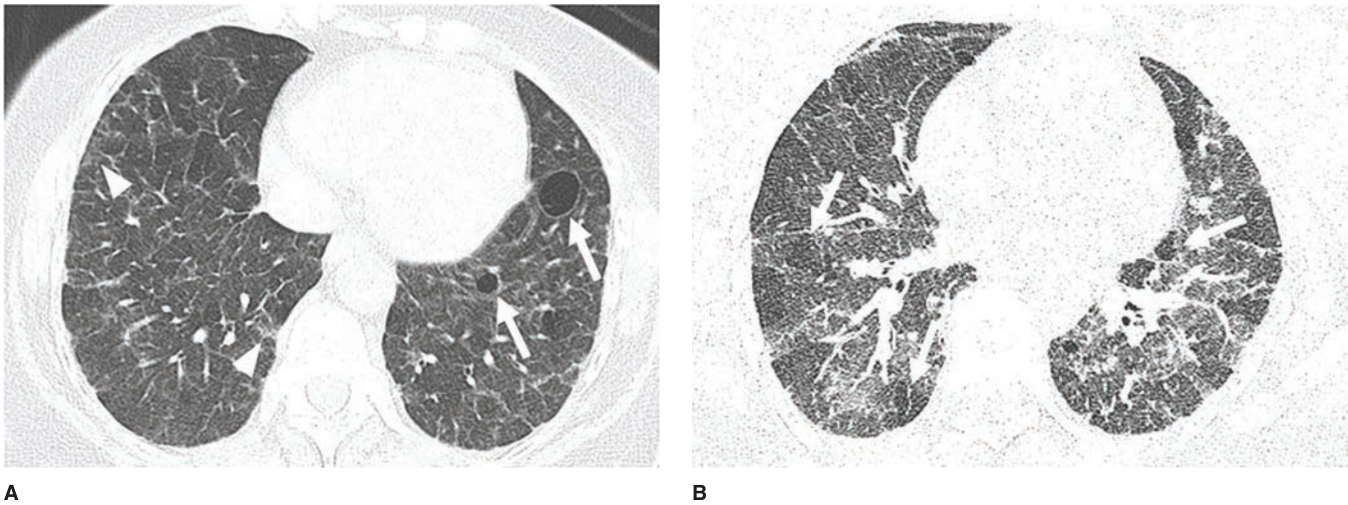

Figure 61-9 Radiologic and histopathologic manifestations in hypersensitivity pneumonitis (HP). **A.** Axial CT chest image in a patient with HP showing scattered cysts *(arrows)* and areas of ground glass attenuation *(arrowheads)*. **B.** Expiratory images from the same patient demonstrate areas of lobular air trapping *(arrows)*. *(continued)*

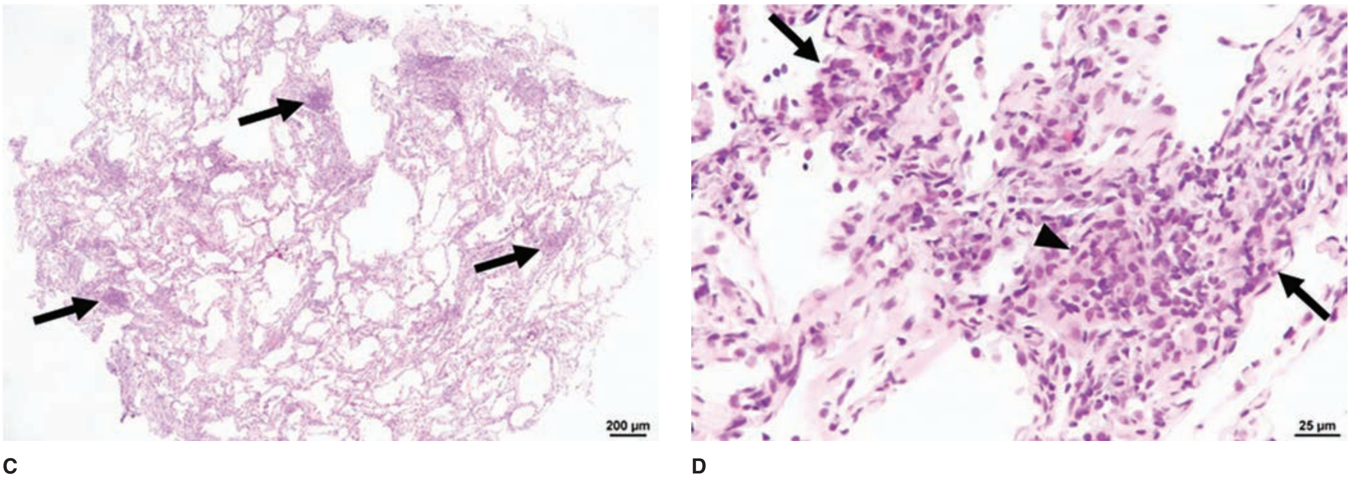

Figure 61-9 *(Continued)* **C.** A patchy cellular chronic inflammatory cell infiltrate *(arrows)* shown to be centered on small airways at higher magnification is present in a histologic image of a transbronchial cryobiopsy obtained from a patient diagnosed with HP. **D.** Higher magnification image shows extension of the lymphoplasmacytic infiltrate with scattered eosinophils into the surrounding alveolar septa *(arrows)* and a focal aggregate of histiocytes forming a loose granuloma *(arrowhead)* that can often be seen in HP.

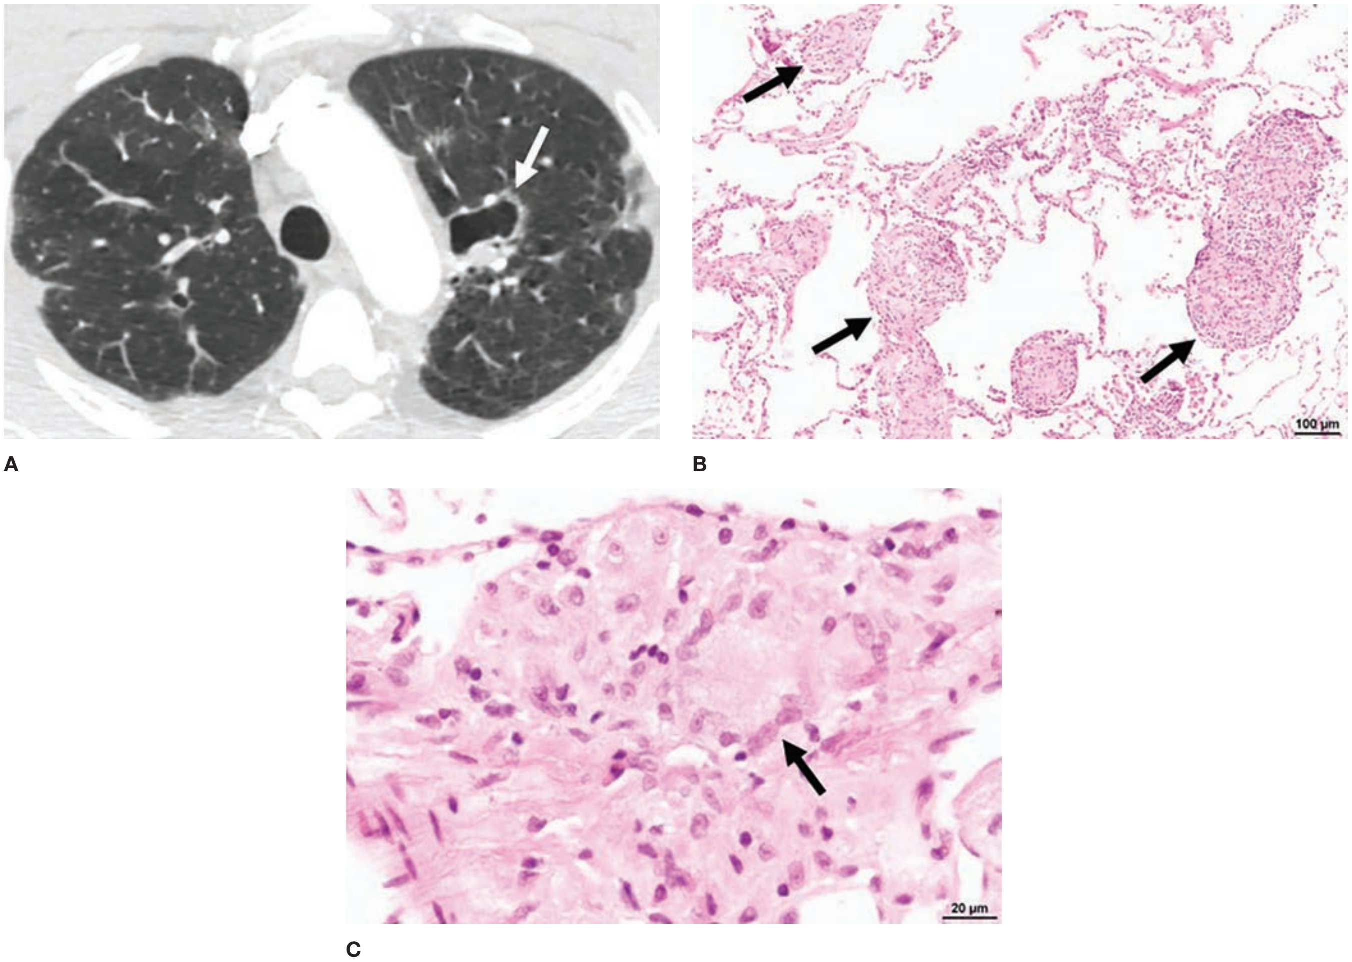

Figure 61-10 Radiologic and histopathologic manifestations in sarcoidosis. **A.** A left perihilar cyst *(arrow)* is seen in this axial CT image obtained from a patient with sarcoidosis. **B.** Tightly formed, well circumscribed, non-necrotizing granulomas confined to the interstitium *(arrows)* and distributed in a lymphangitic pattern is the classic histologic manifestation of sarcoidosis. **C.** A higher-magnification image shows the epithelioid histiocytes and multinucleated giant cells *(arrow)* constituting the granulomas.

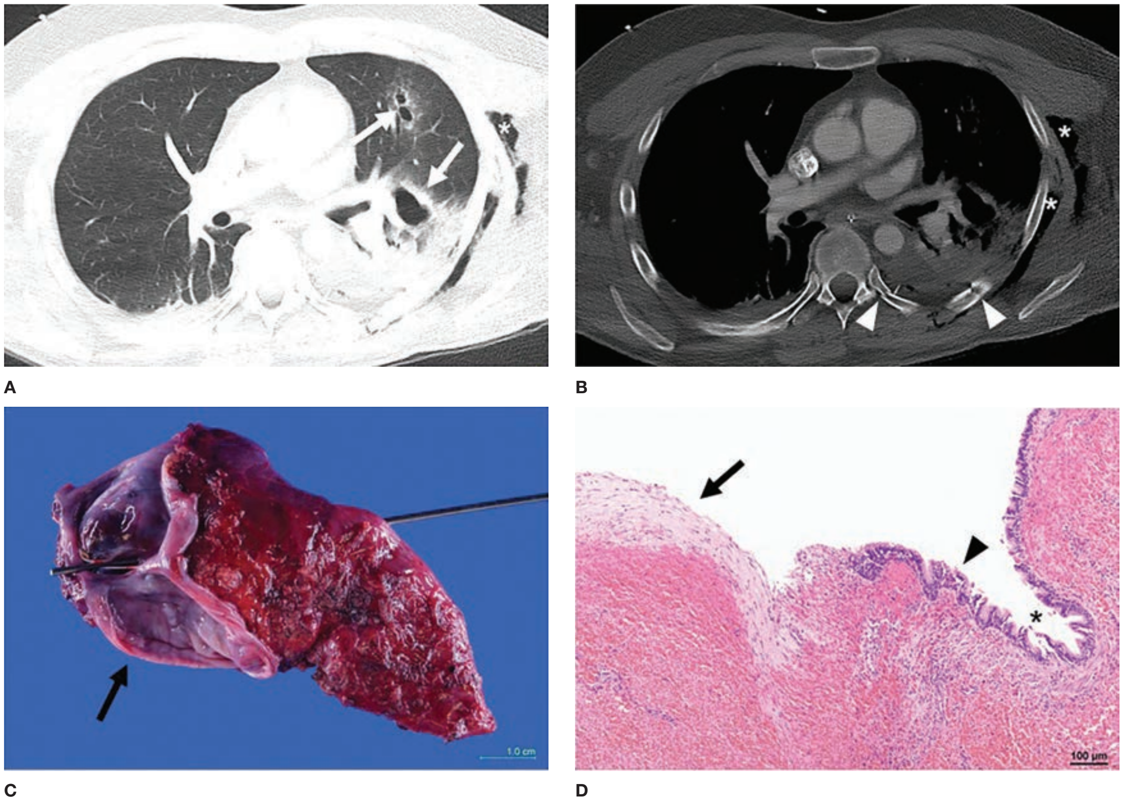

Figure 61-11 Radiologic and histopathologic manifestations of pneumatoceles. **A,B.** Axial CT lung (**A**) and bone (**B**) window images obtained from a patient with thoracic trauma showing traumatic pneumatoceles in the left lung *(arrows)* with surrounding pulmonary contusion along with displaced left rib fractures *(arrowheads)* and subcutaneous gas *(*)*. **C.** Gross anatomic image of a 4-cm, opened, air-filled cystic lesion *(arrow)* resected from an infant that was discovered during an evaluation for infection. A probe extending from the hilar bronchus to the cyst lumen demonstrates a communication between the cyst and the conducting airways. **D.** Histologic image showing the communication between the cyst with a fibrous wall lacking an epithelial lining *(arrow)* and a bronchiolar lumen *(*)* lined by ciliated bronchiolar epithelium *(arrowhead)*. The histopathologic features together with the clinical and radiographic findings were consistent with a postinfectious pneumatocele.

MISCELLANEOUS DIFFUSE CYSTIC LUNG DISEASES

Formation of pneumatoceles, whether due to infectious etiologies (discussed previously), blunt trauma,[137] or accidental aspiration of petroleum products during fire-eating/fire-blowing demonstrations,[138] can result in the formation of multiple pulmonary cysts (Fig. 61-11A and C). Pneumatoceles are acquired air-filled cysts that are thought to develop from leakage of air from a conducting airway into a region of parenchymal injury. Thus, pneumatoceles can expand rapidly to compress the surrounding lung and may rupture into the pleural cavity forming a pneumothorax. The walls of a pneumatocele are typically composed of organizing fibrous tissue without an epithelial lining that differentiates them from true cysts (Fig. 61-11D). Pneumatoceles generally tend to follow a benign course and resolve over time either spontaneously (in the case of trauma and fire-eater's lung) or with appropriate antimicrobial treatment (in the case of infectious pneumatoceles).[77] Hyper-IgE syndrome is a rare primary immunodeficiency syndrome caused by mutations in the signal transducer and activator of transcription 3 (*STAT3*) gene that is characterized by recurrent skin and sinopulmonary infections.[139] Cystic pulmonary changes can be seen in patients with hyper-IgE syndrome and likely represent infectious pneumatoceles due to staphylococcal infections.[77]

DIAGNOSTIC AND MANAGEMENT APPROACH

DCLDs are typically discovered in one of the following scenarios: (1) patients presenting with chronic dyspnea on exertion, (2) acute presentation due to a complication such as spontaneous pneumothorax, (3) detected via targeted screening, for example by a screening chest CT in adult women with tuberous sclerosis complex (TSC), or (4) incidentally discovered on imaging performed for unrelated reasons. An integrated diagnostic approach that includes thorough history-taking and physical examination, critical review of the chest imaging, and detailed histopathologic evaluation and/or genetic analysis in some cases is essential to achieve the correct diagnosis and avoid delays in patient management.

■ History

Comprehensive history-taking provides invaluable information that can assist in rendering the correct diagnosis when evaluating a patient with DCLD. Acute onset of symptoms, especially when associated with other constitutional symptoms such as fever, weight loss, etc., can point towards an infectious etiology. Exposure to cigarette smoke can suggest underlying smoking-related DCLDs. The presence of sicca symptoms can help diagnose underlying connective tissue disorders such as Sjögren syndrome. Patient demographics may make certain diseases more likely than others. For instance, developmental disorders such as CPAM and bronchopulmonary dysplasia are more commonly identified in childhood. LAM is almost exclusively restricted to adult women.[140] Detailed family history may also provide important clues. For instance, a family history of skin lesions, kidney tumors, or spontaneous pneumothoraces can suggest a diagnosis of BHD or TSC-LAM in a patient with DCLD.[59]

■ Physical Examination

While findings on pulmonary examination are typically not specific enough to help establish a firm diagnosis, extrapulmonary physical exam findings may provide important information. Careful skin examination may reveal characteristic dome-shaped papules on the face, neck, and upper torso in patients with BHD.[4] Patients with TSC often have facial angiofibromas, hypomelanotic macules, Shagreen patches, and subungual fibromas.[141] Distinct facial features or joint abnormalities such as hyperextension can be seen in connective tissue disorders such as Marfan and Ehlers-Danlos syndrome.

■ Laboratory Evaluation

Certain laboratory tests can help establish the diagnosis of DCLDs and obviate the need for invasive procedures such as lung biopsies. Elevated serum vascular endothelial growth factor D (VEGF-D) levels can be seen in 60% to 70% of patients with sporadic LAM, and levels ≥800 pg/mL are almost 100% specific in distinguishing sporadic LAM from other DCLDs.[110,142,143] Autoimmune serologies such as antinuclear antibody (ANA), anti-Ro/SSA, and anti-La/SSB antibodies, can help diagnose underlying connective tissue disorders such as Sjögren syndrome. Quantitative serum immunoglobulin levels can help suggest underlying immunodeficiency disorders such as CVID, and abnormal serum free light chain ratio can point toward LCDD. Lastly, peripheral blood and/or buccal swab genetic testing can be helpful in establishing the diagnosis in diseases harboring germline mutations, such as *FLCN* testing for evaluation of BHD.[77]

■ Radiologic Assessment

Critical review of the morphology, profusion, and distribution of cysts, along with careful attention to other noncystic findings on HRCT, is the most important noninvasive means to ascertain the underlying diagnosis in a patient with DCLD. Expert radiologists and pulmonologists familiar with DCLDs can accurately identify the common DCLDs such as LAM, BHD, and FB/LIP in approximately 80% of the cases, based on a critical review of the HRCT features alone.[57] Although DCLDs have a broad differential diagnosis (Table 61-2), it is often easy to exclude certain disorders where cystic change is associated with other radiologic

TABLE 61-4 Summary of Clinical, Radiologic, and Pathologic Features of Major Diffuse Cystic Lung Diseases

	LAM	PLCH	BHD	LIP/FB	Amyloidosis/LCDD
			Clinical Features		
Features	Dyspnea Pneumothorax Chylothorax	Dyspnea Cough Pneumothorax Constitutional symptoms such as fatigue, weight loss and fever	Pneumothorax	Dyspnea Symptoms suggestive of underlying etiologies such as sicca symptoms associated with Sjögren syndrome	Dyspnea Cough
Typical age at diagnosis (years)	20–40	20–40	30–40	Variable	Variable
Gender	F>>>M	F = M	F = M	F>>M	Unknown
Smoking	—	+++	—	—	—
Family history	± Absent in sporadic LAM Autosomal dominant in TSC	—	++ (Autosomal dominant)	—	—
Pneumothorax risk	+++	++	+++	Unknown, almost certainly less than LAM, BHD, and PLCH	Unknown, almost certainly less than LAM, BHD, and PLCH
Extrapulmonary manifestations	AMLs, lymphadenopathy, lymphangioleiomyomas, chylous effusions, TSC and its associated systemic manifestations such as seizures, cognitive impairment, skin lesions, etc.	Diabetes insipidus Bone lesions Skin rash	Skin fibrofolliculomas Renal tumors	Sicca symptoms Other varying manifestations according to underlying disease such as arthralgia, synovitis, skin rash, Raynaud, frequent infections, etc.	Lymphoproliferative disorders, renal failure, systemic amyloidosis, hematologic malignancies, Sjögren syndrome
			HRCT Features		
Cysts					
Distribution	Diffuse, random	Upper and middle lung zones; spares costophrenic angles	Basilar, subpleural, especially the paramediastinal regions, also tend to abut vessels	Diffuse, random, often with eccentric vessels	Diffuse, random
Shape	Round, uniform	Bizarre, irregular, variable wall thickness	Elliptical, lentiform	Round, variable; may contain internal structure/septations	Round, variable
Size	2 mm to 2 cm	Variable, 2 mm to 2 cm	Variable, 2 mm to >3 cm	Variable, 3 mm to >3 cm	Variable, 4 mm to >5 cm

(continued)

TABLE 61-4 Summary of Clinical, Radiologic, and Pathologic Features of Major Diffuse Cystic Lung Diseases *(Continued)*

	LAM	PLCH	BHD	LIP/FB	Amyloidosis/LCDD
HRCT Features					
Nodules	± Absent in sporadic LAM Common in patients with TSC-LAM where they represent a benign condition known as multifocal micronodular pneumocyte hyperplasia (MMPH)	++ Micro and macro nodules with or without cavitation	—	± Centrilobular, usually micronodules Larger nodules may be suggestive of underlying MALT lymphoma	+++ Nodules—can be large
Ground glass opacities	— Except in rare circumstances where they may represent chylous congestion of the pulmonary parenchyma	— Except in patients with concomitant smoking related pathologies such as DIP	—	+++	—
Other HRCT findings	Pleural effusions in ≤20% of patients Effusions more common in sporadic LAM than TSC-LAM	Reticulations	—	Interlobular septal thickening, air-trapping	Lymphadenopathy
Diagnostic Testing					
Laboratory	Serum VEGF-D	Serum and urine studies for diabetes insipidus	*FLCN* mutation analysis	Polyclonal dysproteinemia ANA, anti-SSA, anti SSB (Sjögren syndrome), HIV, quantitative immunoglobulins	Monoclonal dysproteinemia, light chain immunoglobulins
Genetic testing	Typically not needed for the diagnosis of sporadic LAM Germline *TSC* mutations in TSC-LAM	*BRAF* and other *MAPK* pathway mutations such as NRAS, MAP2K1, etc.	Germline *FLCN* gene mutation	—	—
Diagnostic yield of transbronchial lung biopsy	>50%	30%–40%	0	Unknown, likely <30%	Unknown, likely not helpful
Typical histopathologic findings on lung biopsy	Cysts and LAM cells positive for melanocytic markers, including HMB-45 in cells with a smooth muscle phenotype, that are typically most prominent around cysts	S100- and CD1a-positive Langerhans cells with intracellular Birbeck granules by electron microscopy; stellate fibrotic scars in late stages	Intraparenchymal, subpleural, and paraseptal cysts that lack abnormal cell proliferations or a significant fibroinflammatory component	LIP: diffuse dense interstitial polyclonal lymphoplasmacytic infiltrate FB: peribronchiolar dense lymphoplasmacytic polyclonal infiltrate with prominent lymphoid follicles containing germinal centers	Amyloid: amorphous protein deposits with fibrillar ultrastructure and apple-green birefringence by Congo red stain viewed under polarized light LCDD: typically monotypic kappa light chain deposition with finely granular ultrastructure lacking apple-green birefringence by Congo red stain and polarized light
Other histopathologic features	Hemosiderin-laden macrophages	Smoking-related changes in the surrounding parenchyma	Skin biopsy showing fibrofolliculomas	Lip biopsy showing focal lymphocytic sialadenitis in Sjögren syndrome	Abdominal fat pad or bone marrow biopsy showing amyloid or light chain deposition

ANA, antinuclear antibody; AML, angiomyolipoma; BHD, Birt-Hogg-Dubé syndrome; BRAF, v-Raf murine sarcoma viral oncogene homolog B; DIP, desquamative interstitial pneumonia; F, female; FB, follicular bronchiolitis; HMB, human melanoma black; HIV, human immunodeficiency viruses; LAM, lymphangioleiomyomatosis; LCDD, light chain deposition disease; LIP, lymphoid interstitial pneumonia; M, male; MALT, mucosa-associated lymphoid tissue; MAPK, mitogen-activated protein kinase; PLCH, pulmonary Langerhans cell histiocytosis; TSC, tuberous sclerosis complex; VEGF-D, vascular endothelial growth factor D.

features such as fibrotic changes seen in other ILDs. It is important to note that solitary or few (1–5) cysts can arise as an aging phenomenon and may not necessarily reflect a pathologic abnormality.[144] The most common DCLDs that present with either pure or primarily cystic change on chest imaging include LAM, BHD, PLCH, and FB/LIP, and in some cases amyloidosis/LCDD (Table 61-4).

■ Pathologic Assessment

Histopathologic evaluation may be required for diagnostic confirmation in cases where the diagnosis remains unclear following detailed clinical, laboratory, and radiologic assessment. It is important to carefully consider the differential diagnosis prior to undertaking invasive diagnostic procedures, as the choice as well as sequence of procedures may vary depending upon the diagnoses under consideration. For instance, in a patient with lower lobe–predominant cysts where BHD may be a likely etiology, one should opt to pursue genetic testing for *FLCN* mutations prior to pursuing lung biopsy. In patients where LAM and/or PLCH is a possibility, transbronchial lung biopsy may provide a reasonable diagnostic yield and obviate the need for surgical lung biopsy.[140,145–147] Although isolated reports have suggested promise, the role of transbronchial cryobiopsy in the evaluation of patients with DCLD needs further investigation.[148] Video-assisted thoracoscopic surgery (VATS)-guided lung biopsy remains the gold standard. Histopathologic features of the most common DCLDs that are encountered in clinical practice are summarized in Table 61-4. Multidisciplinary integration of histopathologic findings with the clinical and radiologic features, as well as a review of histopathologic findings by an expert pathologist familiar with the nuances of DCLDs, is critical to ascertain the correct diagnosis.

■ Diagnostic Approach

We recommend a stepwise approach progressing from the least invasive to most invasive diagnostic modalities when evaluating patients with DCLD. For instance, in patients with mild disease, who have no or minimal symptoms with preserved PFTs and are comfortable with some degree of uncertainty, it may be reasonable to serially monitor the trajectory of disease progression and not pursue invasive diagnostic procedures. It is also important to distinguish true cysts from cyst mimics such as emphysema and cystic bronchiectasis. Once established as true cysts, we separate patients into paucicystic versus multicystic disease based on the number of cysts (≤10 vs. >10). Proposed stepwise diagnostic algorithms for evaluation of DCLDs are presented in Figs. 61-12, 61-13, and 61-14.[149]

■ Management

While management of specific DCLDs is tailored to the underlying diagnosis (e.g., mTOR inhibitors for LAM [see Chapter 60], smoking cessation for PLCH [see Chapter 59], renal cancer screening

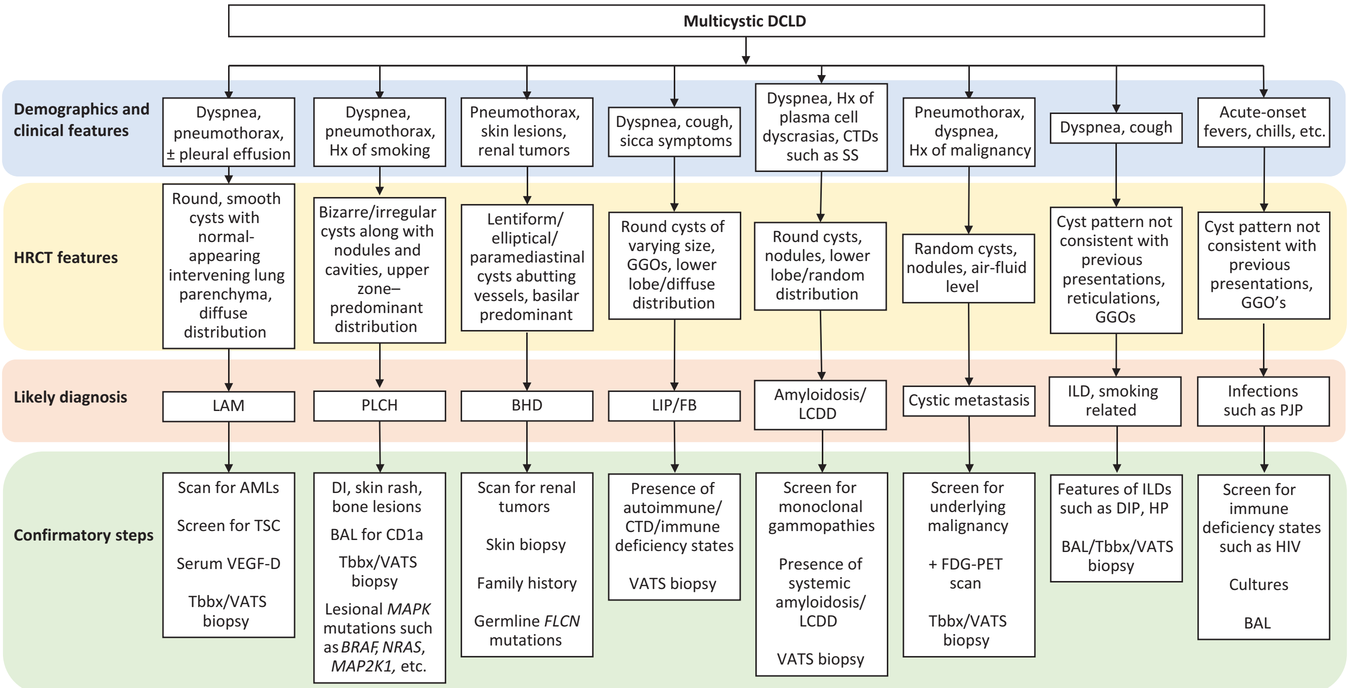
for BHD [discussed above]), there are certain aspects of management that are common to all DCLDs. Cigarette smoking as well as exposure to other inhaled drugs such as marijuana should be strongly discouraged. Patients should be advised to stay up to date on vaccinations such as influenza and pneumococcal vaccinations. Trial of inhaled bronchodilators is appropriate in patients with an obstructive defect on spirometry, with continued use in patients who derive symptomatic benefit.

The presence of DCLDs predisposes patients to an increased risk of developing spontaneous pneumothorax. Patients should be educated about the signs and symptoms of spontaneous pneumothorax and advised to seek immediate medical attention if they experience



Multicystic DCLD
Demographics and clinical features
Dyspnea, pneumothorax, ± pleural effusion
Dyspnea, pneumothorax, Hx of smoking

Figure 61-14 Algorithm to guide approach to the diagnosis of multicystic lung diseases. AML, angiomyolipoma; BAL, bronchoalveolar lavage; BHD, Birt-Hogg-Dubé syndrome; BRAF, v-Raf murine sarcoma viral oncogene homolog B; CT, computed tomography; CTD, connective tissue diseases; DCLD, diffuse cystic lung disease; DI, diabetes insipidus; DIP, desquamative interstitial pneumonia; FB, follicular bronchiolitis; FDG-PET, 18-Fluoro deoxy positron emission tomography; FLCN, folliculin; GGOs, ground glass opacities; HP, hypersensitivity pneumonitis; HRCT, high-resolution computed tomography; ILD, interstitial lung disease; LAM, lymphangioleiomyomatosis; LCDD, light chain deposition disease; LIP, lymphoid interstitial pneumonia; MAPK, mitogen-activated protein kinase; PJP, *Pneumocystis jirovecii* pneumonia; PLCH, pulmonary Langerhans cell histiocytosis; SS, Sjögren syndrome; Tbbx, transbronchial biopsy; TSC, tuberous sclerosis complex; VATS, video-assisted thoracoscopic surgery; VEGF-D, vascular endothelial growth factor D. *(Reproduced with permission from Gupta N, Wikenheiser-Brokamp KA, McCormack FX: Diffuse Cystic Lung Diseases. Respiratory Medicine. Cham: Humana Press; 2021.)*

these symptoms. Consideration should be given to early pleurodesis following the first episode of spontaneous pneumothorax rather than waiting for a recurrent episode due to the extremely high risk of recurrence following conservative management.[42,61,140,150–152] It is worth noting that spontaneous pneumothorax is commonly a presenting manifestation of DCLDs, and performing a screening chest CT when evaluating patients with a pneumothorax has been shown to be cost effective.[153–155] The risk of air travel–related spontaneous pneumothorax in patients with DCLDs is approximately 1 episode per 100 flights. Thus, it is generally safe for the majority of patients with DCLDs to undertake air travel.[42,152,156–158] Although there is a paucity of direct evidence, patients should be advised against scuba diving.[63,149]

CONCLUSIONS

DCLDs comprise multiple heterogenous disorders that by virtue of their unique etiopathogenic mechanisms, clinical presentation, radiologic features, and natural history are worthy of an independent classification of their own, distinct from the typical infiltrative/fibrotic ILDs. Although multiple diseases can produce pulmonary cysts, only a few disorders present with DCLD as the primary pulmonary manifestation. Ascertaining the correct diagnosis is of paramount importance, as disease-modifying treatments are increasingly becoming available for specific DCLDs. Transformative progress in DCLDs has been driven by synergy between scientists, clinicians, and patients. This model can be used as a blueprint to meaningfully advance the field in other rare as well as common pulmonary disorders.

CHAPTER 62

Benign Metastasizing Leiomyoma

Gustavo Pacheco-Rodriguez

INTRODUCTION

Benign metastasizing leiomyoma (BML) is a rare disease of women. It is characterized by noninvasive, nonaggressive, well-circumscribed, single or multiple tumors composed of differentiated smooth muscle cells, localized to sites other than the uterus in patients with uterine leiomyomas[1–7] and, in some cases, adnexal tumors.[8] BML has been identified in lungs[3] and lymph nodes[9] which, in addition to uterine leiomyomas, are the most common sites involved. BMLs have also been identified in the mediastinum,[10,11] retroperitoneum,[12] vascular channels,[13] bone,[14,15] heart,[16] skeletal muscle,[17] spine,[18] and pancreas.[19] Pulmonary BML is usually asymptomatic and presents with either single or multiple lung nodules of varying sizes[20] found incidentally on chest x-ray or computed tomography (CT) imaging. Occasionally, patients present with mild or severe pulmonary symptoms due to BML. Most patients with BML have undergone uterine myomectomy or hysterectomy due to leiomyomas.[3,6,21,22]

The first report of BML in 1939 described a 36-year-old woman who presented with dyspnea and wheezing. Chest radiograph showed multiple lung nodules. At autopsy, lymph nodes, uterus, and lungs showed nodules composed of smooth muscle cells with identical morphology,[23] and the term *metastasizing fibroleiomyoma of the uterus* was adopted. This term was later abandoned, and the name BML was proposed because of the metastatic behavior of this disease.[3]

BML represents a diagnostic and therapeutic challenge because of its pathogenesis and metastatic potential.[3] The diagnosis should be considered in a premenopausal woman with a history of uterine leiomyoma. Patients with BML are treated by managing estrogens, either surgically or pharmacologically.[24]

EPIDEMIOLOGY

Pulmonary BML is a rare disease of unclear prevalence. More than 100 cases of BML have been reported, but the number of reports has been rising steadily over the past decade as BML is increasingly recognized; only a few studies have reported more than one case.[3,25,26] BMLs have been identified worldwide. There is no apparent ethnic or racial predominance, in contrast to uterine leiomyoma, which is more frequent in African-American women.[27,28] Countries with reports of BML are geographically diverse[6,26] and include the United States,[21] Portugal,[29] Brazil,[30] China,[31] India,[18] South Korea,[17] Japan,[32] and Turkey.[9] BML is found primarily in premenopausal women who have undergone surgical procedures for treatment of uterine leiomyomas;[3,6,33] however, there are cases of lung BML in women with no history of these surgeries.[21] The majority of BML cases were reported in premenopausal women. Reports of BML in men and children[34] have been exceedingly rare.

CLINICAL PRESENTATION

BML lung nodules have been detected in women from a few months to greater than 30 years after they have undergone uterine myomectomy or hysterectomy.[35] Although most of the reports describe BMLs in patients following these procedures, several cases have been reported in women with no such history.[3] Furthermore, there are reports of BMLs diagnosed in women prior to myomectomy or hysterectomy.[5,21,36]

Most cases of lung BML have been identified as an incidental finding on imaging procedures performed for other purposes (Fig. 62-1).[3] Occasionally, BML in younger women presents with respiratory symptoms,[37,38] including cough, wheezing, dyspnea, and pleuritic chest pain.[20,21,23,39,40] The symptoms typically follow an indolent course, but some aggressive cases have been reported.[41] Lungs and lymph nodes are the most common sites of BML, but BML can also be present in the mediastinum, retroperitoneum, vascular channels, bone, heart, skeletal muscle, spine, and soft tissues.[14,17,42] The symptoms of BML depend on the site of the metastasis.[25,43,44] Patients with BML and spine involvement can present with leg pain and paresthesia.[42] BMLs in other sites, such as uterus, heart, and lymph nodes have been described, for

Figure 62-1 Nodular structures in BML. Favorable response to antigonadal therapy for a benign metastasizing leiomyoma. Obstet Gynecol. 2012;119(2 Pt 2):438–442.)*

the most part, as asymptomatic.[3] Symptoms of uterine fibroids, which are highly associated with pulmonary BML, may include abnormal uterine bleeding, pelvic pressure/pain, and reproductive dysfunction.[23,40] Recent reports highlight a potential association of melanoma and other cutaneous tumors with smooth muscle cell tumors and BML in a tumor-to-tumor metastasis model;[45] therefore, BML should be considered in a patient with melanoma and lung nodules.[46]

Clinical findings of BML may include pneumothorax,[21,47–49] hemothorax,[50] and pleural effusion;[51] in one case, BML co-presented with pulmonary arteriovenous malformation (PAVM).[52] However, in most cases, the sole findings are single or multiple unilateral or bilateral tumors with no specific lobar distribution (Fig. 62-2);[20,53,54] occasionally, BMLs have been shown to present in a miliary pattern.[55] The nodules can be solid, cystic, or complex.[21,56] The presence of pneumothoraces and cysts in patients with BML can lead to misdiagnosis as lymphangioleiomyomatosis (LAM), a multisystem disease characterized by the presence of lung cysts surrounded by proliferative smooth muscle–like cells.[57] In fact, the World Health Organization classification of lung tumors currently does not include BMLs but does include LAM lesions.[58] BML can also be misclassified as a low-grade leiomyosarcoma.[59] A number of different types of uterine tumors (e.g., leiomyoma, smooth muscle tumors of uncertain malignant potential, leiomyosarcomas, other smooth muscle tumors, endometrial stromal tumors) may be mistakenly given a diagnosis of BML. A final diagnosis, therefore, may be challenging, and requires medical history and pathologic analysis of biopsies or surgically removed tumors.

PATHOLOGY

Pathologically, BML lung nodules resemble hamartomas (the most common benign lung tumor), low-grade leiomyosarcomas, and nodules of proliferating smooth muscle cells.[60] Leiomyomas can be classified as benign or malignant, based on the number of mitotic figures. Leiomyosarcomas have more than 5 mitotic figures per 10 high-power field (HPF), whereas benign lesions have less than 5 mitotic figures per 10 HPF.[61] BML lesions contain less than 5 mitotic figures per 10 HPF, consistent with their benign nature.[25,61] BML lesions consist of well-differentiated, proliferative, benign smooth muscle cells that form intersecting fascicles and are characterized by low cellularity, low mitotic index, and no nuclear atypia (Fig. 62-3). The lesions form well-circumscribed nodules, ranging in size from a few millimeters to several centimeters in diameter.[3,6] The growth of the BML tumors is slow and, in many cases, there is no apparent size change, over long periods of time, of the multiple nodules detected by radiographic techniques. The BML nodules do not invade the surrounding tissue and may be necrotic.[33] BML tumors express smooth muscle proteins such as smooth muscle actin, desmin, and caldesmon[6,62] and most also express receptors for estrogen and progesterone, similar to uterine leiomyomas.[3,5,26] Lungs are common organs for metastasis of cells from different organs,[63,64] but as mentioned above, these tumors, including BML, can present in multiple sites (e.g., lung, lymph nodes, heart, skeletal muscle).

BML lung nodules have distinct pathologic characteristics that differentiate them from other benign lung tumors. BML nodules contain vascular structures as determined by reactivity to anti-CD34 antibody.[3,62,65] They also show reactivity with antibodies against proliferating cell nuclear antigen (PCNA), which appears in a different pattern from that seen in leiomyomatous hamartoma.[66] They express variable levels of p53, although the role of this tumor suppressor in BML cells has not been reported.[62] Most of the histopathologic sections of lung BML are not reactive with the monoclonal antibody human melanoma black 45 (HMB-45),[21,67,68] which recognizes Pmel17,[62] a melanosomal protein expressed in cells from lung hamartomas, PEComas (perivascular epithelioid cell tumors of the uterus that can metastasize to the lung[69]), and lymphangioleiomyomatosis (LAM).[70] There have been many attempts to immunologically characterize BML nodules, but these have been nonproductive since BML smooth muscle cells are not reactive with antibodies to common antigens (e.g., EMA, CD10, CD117, TTF-1, BCL-2 GPAP, S-100, calretinin, cytokeratin, chromogranin) examined in histologic clinical laboratories.

It is possible to identify cancer cells based on their molecular phenotype;[71,72] however, knowledge of the molecular characteristics of BML cells is incomplete. Expression of the micro-RNA 221 (miR-221), which has been correlated with malignancies,[73] can differentiate leiomyosarcoma from BML.[73] On the other hand, BMLs proliferate without telomeric changes, suggesting that their proliferative behavior is independent of telomeric attrition, a feature of malignant diseases.[74,75] Cytogenetic studies of BML lung tumors have shown that the cells have abnormalities in several chromosomes. The proliferative behavior of BML cells correlates with chromosomal translocations present in other noninvasive tumors.[76–78] For example, BML tumors from five cases showed 19q and 22q terminal deletions.[76] In addition, loss of chromosomes 3q and 11q has been reported.[79] These chromosomal changes differ from those reported more frequently in uterine leiomyomas, which involve translocations of chromosomes 12q14-15 and deletion of chromosome 7.[80] Interestingly, a single case showed multiple chromosomal deletions from cells isolated from several metastatic sites (e.g., thigh, lung pleura, uterus).[77,81] Rearrangement of the 6p21 region was correlated with changes in the *high-mobility group A1* gene (*HMGA1*).[77] Chromosomal translocation and mutations have been associated with high-mobility group protein isoform C (HMGIC) in leiomyomas,[82–84] but they have not been identified in the leiomyomas present in BML patients.

PATHOGENESIS

Benign lung nodular or mass lesions may be of either epithelial or mesenchymal origin.[85] BMLs have been classified as benign tumors of mesenchymal origin, but the specific cell type from which the tumors originate is unknown. Hamartomas, the most common lung tumor, are seen in both genders and, as mentioned above, may have a different histopathology from BML. Since most of the BML cases are discovered after hysterectomy or myomectomy and are strongly associated with uterine leiomyomas,[3] it is thought that BMLs mostly likely originated from a uterine cell type. There are few BML cases reported where the cells showed lack of estrogen or progesterone receptors, suggesting a nonuterine origin;[26] however, it is also possible that the proteins were downregulated due to high levels of ligands. Although there are different types of leiomyomas (e.g., mitotically active, cellular, hemorrhagic cellular, atypical, epithelioid, myxoid, vascular, lipoleiomyoma),[86] the type of leiomyoma associated with BML has not been determined. For example, PEComas of the uterus with pulmonary metastases may have a similar presentation to BML, but these tumors express Pmel7, which is recognized by the monoclonal antibody HMB-45 that reacts with LAM lung nodules.[87–89]

Genetic studies have supported a close relationship between BML nodules and leiomyomas. Whole-exome sequencing of BML nodules and patient-matched uterine leiomyomas has shown identical point mutations and copy number aberrations in all tumors, which were absent in the peripheral blood of each patient.[90,91] Clonality assays of X-chromosome inactivation and balanced karyotype studies confirm that BML lesions are probably of clonal origin and are closely related to uterine cells.[92,93] In addition, case studies identified somatic mutations in pulmonary BML that were absent in blood and leiomyomas, suggesting potential genetic drivers of metastasis in BML, such as PTEN.[90]

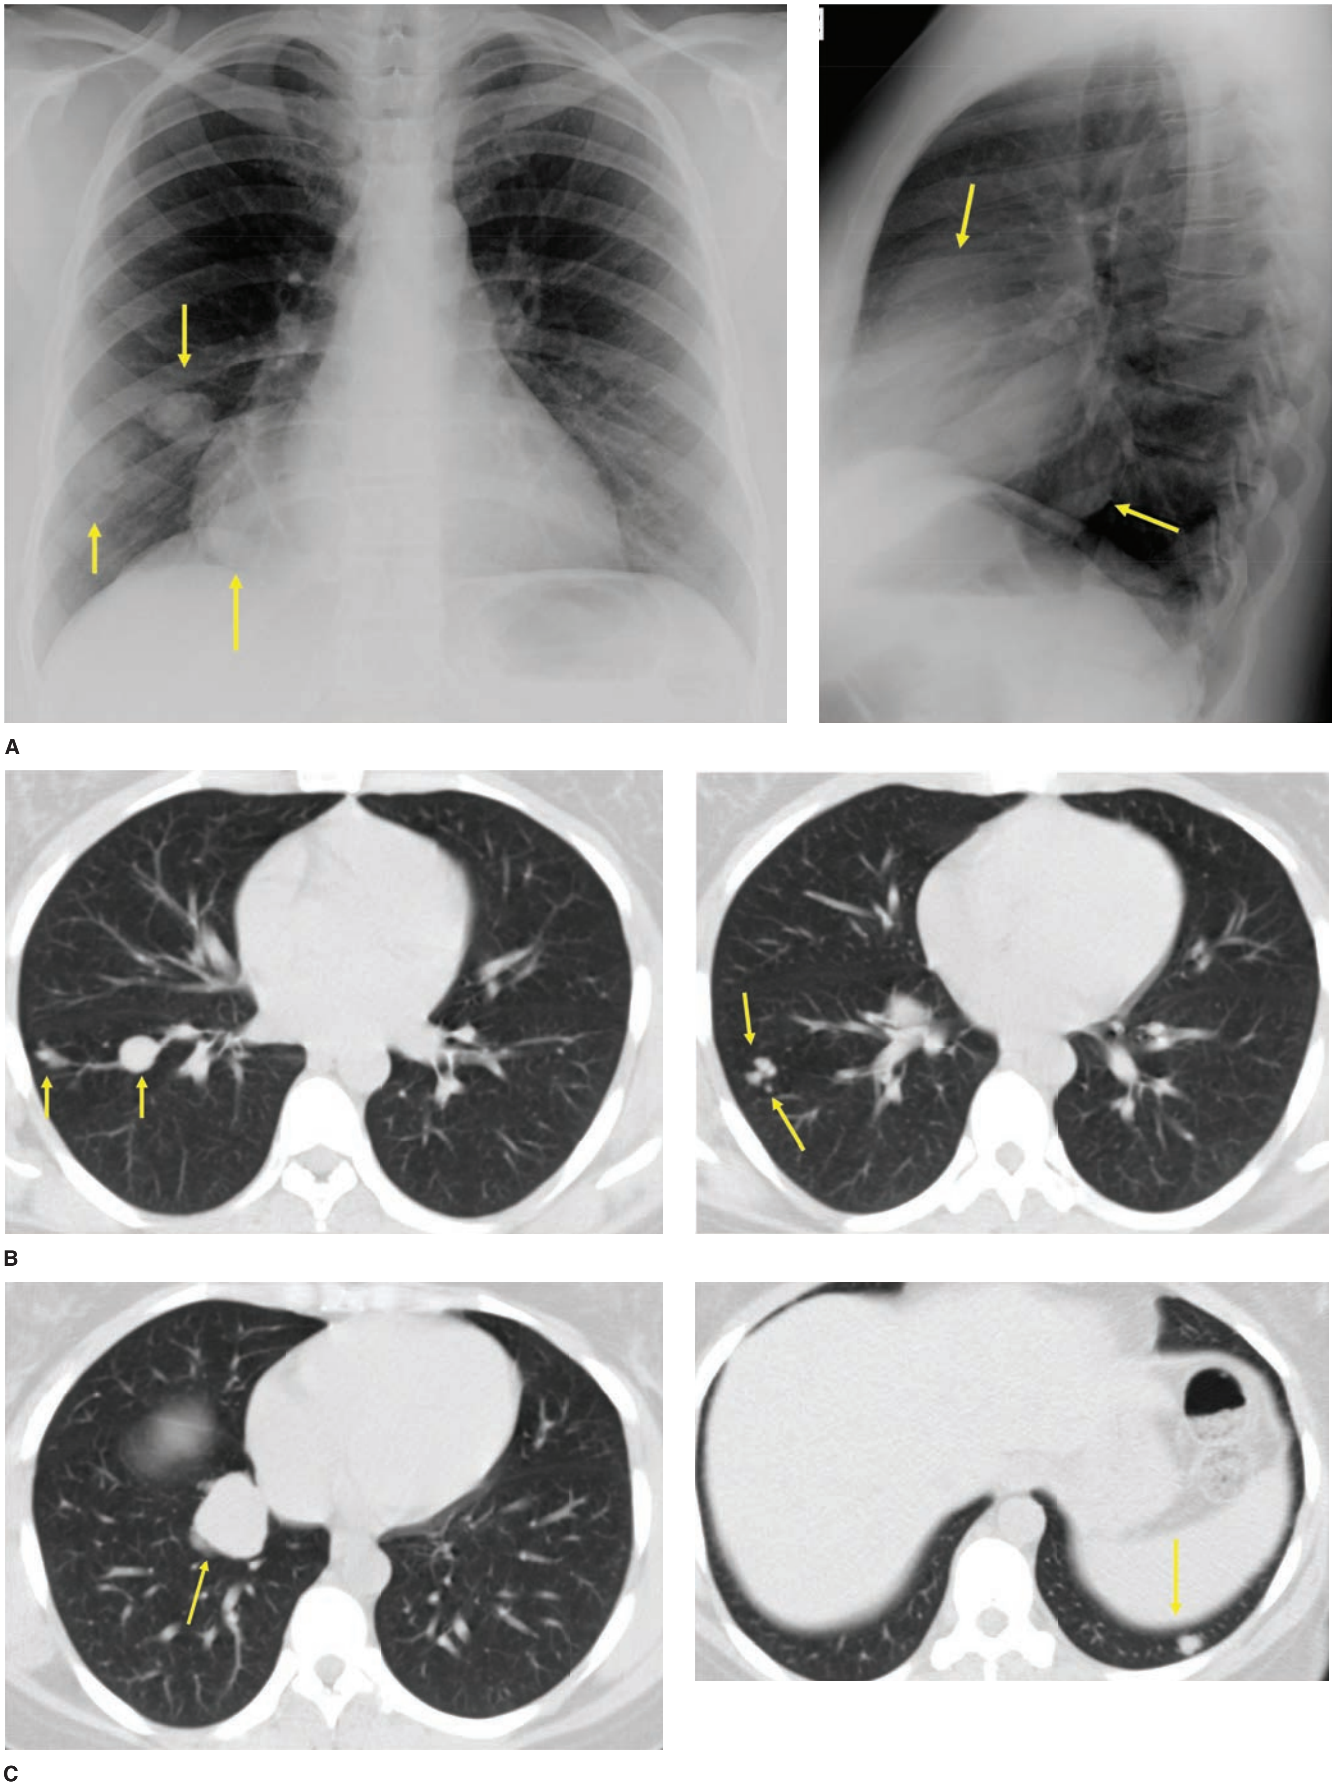

Figure 62-2 A 37-year-old woman with biopsy proven BML. Chest radiograph (**A**) and CT images (**B** and **C**) demonstrate well-circumscribed lung nodules of varying size. Arrows indicate nodules. *(Reproduced with permission from Dr. Ami Rubinowitz, Yale University School of Medicine, Radiology and Biomedical Imaging.)*

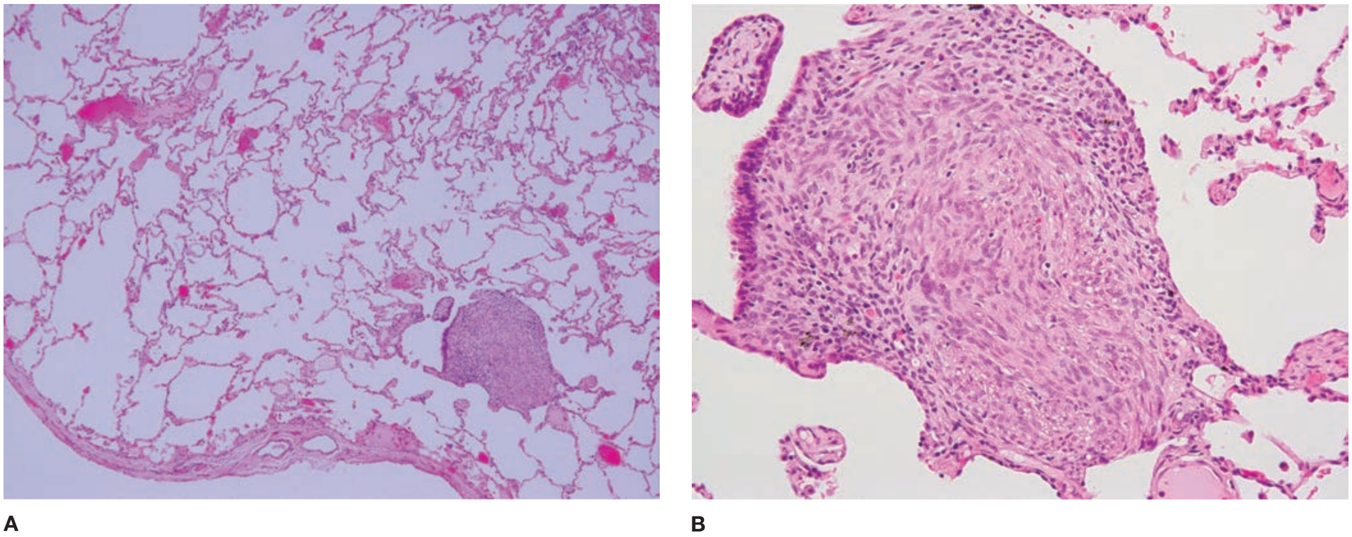

Figure 62-3 Histologic section of proliferative areas of lung BML. Tissue section shows proliferative smooth muscle cells forming fascicles characteristic of leiomyomas and BML. Panels **A** and **B** show low- and high-resolution pictures of proliferative nodules of lung BML. *(Reproduced with permission from Taveira-DaSilva AM, Alford CE, Levens ED, et al. Favorable response to antigonadal therapy for a benign metastasizing leiomyoma. Obstet Gynecol. 2012;119(2 Pt 2): 438–442.)*

Despite the growing body of evidence supporting a uterine origin of BML, its precise etiology is still debated. It has been proposed that cells responsible for the formation of pulmonary BML are derived from (1) low-grade tumors; (2) cells dislodged from uterus at the time of myomectomy and hysterectomy; (3) metastasis from uterus or an unknown site; (4) proliferation of lung smooth-muscle cells; and/or (5) simultaneous, independent development of multiple leiomyomas.

Low-grade tumors: Although other tumors may occur in patients with BML including leiomyosarcoma, adenocarcinoma, breast carcinoma, and skeletal muscle tumors,[3] their association with BML is not clear. Leiomyomas of the esophagus, lung, and uterus are found in association with multiple endocrine neoplasia type I (MEN1), but loss of heterozygosity for MEN1 has not been investigated in BML.[94] Tumors characterized as low-grade leiomyosarcomas and high-grade leiomyosarcomas do not appear to metastasize to the lung; these tumors occur mainly in the abdominal cavity.[95] It has also been proposed that BML could be an intermediate tumor stage, leading to a malignant leiomyosarcoma,[10] but high-grade leiomyosarcomas involving the lung reappear in a short period of time following surgery.[95] Low-grade leiomyosarcomas do not express progesterone and estrogen receptors, as is the case in BML.[96] Thus, it is unlikely that BMLs arise from low-grade malignancies.

Cells dislodged from uterus at the time of myomectomy and hysterectomy:

Since pulmonary BML has been associated with hysterectomy and myomectomies, it has been postulated that some of the uterine cells move into the blood circulation at the time of surgery and migrate to the lung where they remain and grow at a slow rate.[33] Lung BML has been associated with tumors in the retroperitoneal cavity,[12] pelvis, and para-aortic lymph nodes, arguing against the passive passage of cells from uterus to lung.[33] The presence of BML tumors in the pelvic region is not in agreement with the concept that uterine cells become dislodged and seed the lung. Although most cases of BML report multiple pulmonary tumors after hysterectomy, a few cases describe the occurrence of nodules before hysterectomy.[97] BML has been correlated with endometriosis, as BMLs and endometriosis have a similar course and may develop after hysterectomy or myomectomy.[5,6] Estrogen and progesterone receptors are found in lung BML cells and uterine leiomyomas, which are the most likely source of the cells. However, it is not clear if lymphatics or blood vessels are involved in the metastatic process, leading to pulmonary BML.

Metastasis from uterus or unknown site: Due to the fact that BMLs are present in multiple sites, it is possible that either uterine smooth muscle cells or cells from other nonuterine sites metastasize to the lung. About 40% of leiomyomas or myomas possess specific chromosomal abnormalities.[92] Uterine leiomyomas comprise smooth muscle cells with the extracellular matrix containing a high collagen content.[98] Lung BML nodules, however, do not have a high content of extracellular matrix. Leiomyomas contain high concentrations of estrogen[99] and progesterone[100] receptors, which drive the proliferation of cells in response to these ligands. In addition, leiomyomas contain large amounts of aromatase,[101] an enzyme involved in estrogen synthesis.[102] The presence of BML leiomyomas in lung, lymph nodes, muscular tissue, heart, vascular structures, retroperitoneal cavity, and parietal pleura[103] suggests a metastatic process.[12,16] Leiomyomas of the uterus do not tend to metastasize to the lung,[104] but BML can present with uterine vascular invasion,[31] supporting a metastatic model. Similar patterns of X-chromosome (human androgen receptor) inactivation[105] suggest that there is primarily a single BML cell source, which is the uterus.

Proliferation of lung smooth muscle cells: BML nodules could originate from proliferative lung smooth muscle cells, as is the case in primary leiomyoma.[106] However, pathologic sections of a primary pulmonary leiomyoma lack immunoreactivity for estrogen and progesterone receptors, as is found in BML.[107]

Simultaneous independent development of leiomyomas at multiple sites: Multiple BML tumors have been identified in some cases, and it is possible that they occur independently or via a metastatic process.[17] Since initial mutations have not been identified, it is possible that the mutations occurred independently in the different sites. Experimental models to study BML are not available, but human uterine cells may help us to understand the disease better.[108] Interestingly, N-nitroso compounds promoted formation of tumors in lung, reproductive and mammary organs.[109] Chronic treatment of mice with N6-(methylnitroso) adenosine (m6(NO)Ado) caused tumors in lungs and reproductive tract.[109] These findings support the hypothesis that BML could be promoted by carcinogenic processes.

Thus, although the origin of the lung BML cells is not completely understood, compilation of all the cases favors a uterine origin.

Metastatic dissemination of BML cells appears to be the most accepted mechanism for localization of BML to the lungs.[3] BML cells could metastasize via the lymphatics, hematologic spread, coelomic metaplasia, and intraperitoneal seeding.[5] Since estrogen appears to play an important role in BML development, estrogens may play a role in mutagenesis, giving origin to BML cells.[110] Extrapolating from knowledge of other metastatic diseases and animal models (e.g., LAM), estrogen may favor BML cells anchoring, seeding, and growing in the lung.[111] Galectins, formerly known as S-type lectins, are soluble and membrane-bound proteins that possess high affinity for β-galactose–containing glycoconjugates, are expressed in almost all organisms, and have been shown to play a role in cell–cell interactions and involved in tumor progression.[112,113] Galectins have been identified in pathologic sections of BML lesions, suggesting that these proteins could play a role in cell transformation, regulation of apoptosis and cell growth, cell adhesion during metastasis, and regulation of tumor invasiveness.[112] Molecular studies support the notion that BML metastasis to the lung is promoted by the inherent properties of BML cells and is not a mere byproduct of the surgical procedures.[114] A genetic and pathologic study showed that BML is clearly distinct from leiomyosarcomas, and common uterine leiomyomas[96] and intravenous leiomyomas are different from BML.

The molecular mechanisms and genetic factors that could contribute to this disease have not been elucidated. Some of the factors potentially involved in the development of uterine leiomyoma are basic fibroblast growth factor (bFGF), transforming growth factor beta (TGF-β), and granulocyte-macrophage colony-stimulating factor (GM-CSF),[115] although a role for these factors in the pathogenesis of BMLs has not been defined. A large number of uterine leiomyomas and some patients with intravenous leiomyoma possess different mutations in the mediator complex subunit 12, MED12,[116,117] which regulates transcription.[118] Due to these and other, yet unknown genetic changes, the behavior of BML, although most commonly benign, is diverse. It has been shown that intravenous leiomyoma may not appear as benign.[119] A case of aggressive BML has been reported with presentation of mutations in lung and uterus.[41] BML cells without a clearly distinct smooth-muscle phenotype may also exhibit unusual growth patterns.[120]

PULMONARY PHYSIOLOGY

Few studies have evaluated lung function in patients with BML.[21,40,95,121,122] In one study, a patient was followed for more than 10 years and serial pulmonary function tests were obtained.[21] Initially, the patient presented with diminished vital capacity and total lung capacity without any evidence of airflow obstruction or impairment in diffusion capacity (Fig. 62-4). As the disease progressed, the patient experienced a decline in diffusion capacity that could have resulted from the decline in lung volumes. In response to antiestrogen therapy, increases in vital capacity and total lung capacity were observed. In this case, the pathophysiologic profile was consistent with that of an interstitial lung disease.

RADIOLOGY

BML nodules may be identified by chest x-rays, CT, positron emission tomography (PET), and magnetic resonance imaging (MRI). The nodular structures observed in BML are well circumscribed. Bilateral pulmonary BML nodules are more common than unilateral nodules. The lung nodules can rarely be cavitating[123] or cause lung cysts.[21] Fluorodeoxyglucose-PET is negative in BML[124] and may be used to differentiate BML from some other tumors. However, many lung malignancies, such as adenomas, bronchoalveolar carcinomas, carcinoid tumors, and low-grade lymphomas also have low glycolytic activity.[125] ^{18}F-FDP-PET can, however, can distinguish BML from leiomyosarcoma, which is a more glycolytically active tumor and may be found in association with BML.[9] Computed tomography and magnetic resonance imaging have also been used to identify BML lesions in the retroperitoneal space and pelvic cavity.[126] Leiomyomas are often large enough to be recognized on pelvic examination; however, the imaging technique of choice to determine the dimensions and locations of the fibroids is a pelvic ultrasound.[127] Since, in most instances, the lung nodules are an incidental finding, a chest x-ray may be warranted after a patient is diagnosed with uterine leiomyomas.

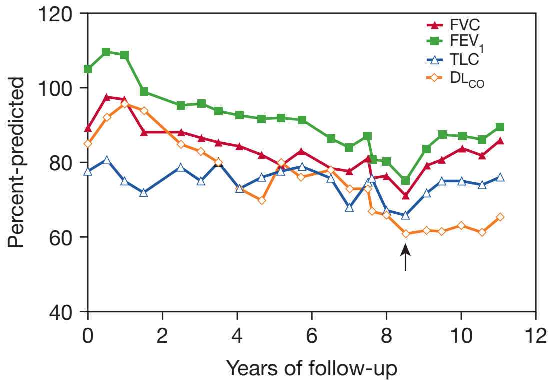

Figure 62-4 Changes in lung function before and after leuprolide acetate therapy. The patient was followed for 8.5 years before therapy and for more than 2 years after therapy. Respiratory parameters—e.g., forced vital capacity (FVC), forced expiratory volume in the first second (FEV_1), total lung capacity (TLC), diffusion capacity for carbon monoxide (DLCO)—declined prior to therapy but improved following treatment with leuprolide. *(Reproduced with permission from Taveira-DaSilva AM, Alford CE, Levens ED, et al. Favorable response to antigonadal therapy for a benign metastasizing leiomyoma. Obstet Gynecol. 2012;119(2 Pt 2): 438–442.)*

DIAGNOSIS

The incidental finding of pulmonary nodules is a common and challenging issue. The primary objectives are to distinguish benign nodules from cancerous ones, as well as to establish a diagnosis. One criterion used to distinguish a benign nodule from a malignant one is the presence of calcification;[128] however, in many cases, this is inconclusive. The size, morphology, and growth rate of the nodules, as well as the risk factors of the patient, need to be considered.[128] A full description of the approach to lung nodules may be found in Chapter 110.

The differential diagnoses of BML nodules include infectious or metastatic lesions[129,130] (Table 62-1). Diagnosis requires a compatible medical history and pathologic analysis of biopsies and/or surgically removed tumor. CT-guided, transbronchial, or open lung biopsy may be used to establish the diagnosis.[61] Pathologic findings of BML are described above. BML patients do not present with dysregulated levels of tumor biomarkers—e.g., carcinoembryonic antigen (CEA); carbohydrate antigen 19-9, also called cancer antigen 19-9 or sialylated Lewis (a) antigen (CA19-9); carcinoma antigen 15-3 (CA 15-3); cancer antigen 125 (CA-125); cytokeratin 19 fragment (CyFRA21-1); neuron-specific enolase (NSE); alpha-fetoprotein (AFP); hyperglycosylated hCG (HCG-β); or beta-2-microglobulin (β2-MG).[130]

Since the lung is one of the main organs involved in metastasis from different types of cancers including colon, breast, pancreas, ovary, and stomach, the presence of either single or multiple lung nodules should always raise suspicion of primary or metastatic malignancy. Thus, differential diagnosis of BML should include primary pulmonary leiomyoma, primary pulmonary leiomyosarcoma, metastatic leiomyomatosis of an extrauterine source, pulmonary

hamartomas, and lymphangioleiomyomatosis (LAM).[3] Lung hamartomas are associated with other cancers and express the melanogenic protein Pmel17,[131] as do LAM lesions.[88,89,132] Low-grade leiomyosarcomas may mimic BML, but they can be distinguished based on lack of expression of progesterone and estrogen receptors.[106] Other diseases presenting with similar lung nodules (Table 62-1) include infectious processes (fungal, parasitic, and bacterial [e.g., tuberculosis]), amyloidosis, mucoid impaction syndromes, multiple arteriovenous malformation, paraffinoma, plasma cell granuloma, rheumatoid nodules, sarcoidosis, and silicosis.[129] The diagnosis of BML should include a complete radiologic and histologic assessment, with focus on the status of estrogen and progesterone receptors.[133]

BML, depending on location, has been classified as intravenous leiomyomatosis and disseminated BML,[12] but there are no reports of lymphatic involvement, as is the case with LAM.[57] Intravenous leiomyomatosis may involve the heart, causing severe symptoms[134] that may be fatal.[135] BML should therefore be considered in cases of tumors of the heart with uterine leiomyoma.[135] It is also important to determine the presence of intravenous leiomyomatosis in the uterine, pelvic, and cardiac veins in the presence of BML, as this has been observed.[136] Leiomyomatosis peritonealis disseminata is one of the diagnoses to consider when a BML patient presents with peritoneal lesions.[12]

PROGNOSIS

The prognosis of patient with BML is generally favorable and may be improved with treatment. The lung lesions are often identified many years after hysterectomy or myomectomy, suggesting that the growth rate of these tumors is slow. However, there have been cases of recurrence and, rarely, of BML progression to leiomyosarcoma.[137] Some experts suggest that women undergoing surgical procedures of the reproductive tract be followed with chest radiographs, although formal guidelines from major clinical consensus statements do not address this. Factors that may influence the prognosis of BML patients include involvement of other sites including heart, veins, or spine, as well as the presence of other cancers. There are only scattered reports of BML as a cause of death.

TREATMENT

Close follow-up of lung BML after treatment is important since lung BML may be difficult to distinguish from other, more aggressive diseases (e.g., leiomyosarcoma, LAM). Treatment involves tumor resection and manipulation of hormonal status.[26] Surgical treatments have been adapted from those used for uterine leiomyoma and include hysterectomy, myomectomy, dilation of the cervix, uterine artery embolization and endometrial ablation, and curettage.[21,26,130] BML tumors also respond to hormone therapy, with resolution of symptoms such as dyspnea.[25] Lung tumors may regress at menopause and during/after pregnancy, supporting a role for estrogen in the pathogenesis of BML.[138]

Oophorectomy has been reported to improve lung function and cause regression of lung tumors.[36,40,121,122,139–142] Although bilateral oophorectomy has been the most commonly used treatment, unilateral oophorectomy has been effective in treating some BML tumors.[36] Another line of treatment has involved antiestrogenic therapy. Gonadotropin-releasing hormone (GnRH) analogues (e.g., leuprolide acetate) have been used to reduce estrogen levels.[13,21,143] Other drugs shown to be effective include the selective estrogen receptor modulators (SERMs) such as raloxifene,[30,121,144] selective progesterone receptor modulators (SPRMs), and aromatase inhibitors such as anastrozole.[121] Progesterone therapy also has proved to be effective.[59,145,146] There have been some cases of BML refractory to progesterone and aromatase inhibitors.[26,38] Treatments of uterine leiomyoma have also included combinations of GnRH analogues with aromatase inhibitors[26,121,147] and antiprogestin (CDB-2914).[26,147] In some cases, total abdominal hysterectomy with bilateral salpingo-oophorectomy (TAH/BSO) has been combined with drugs.[26] It is important to consider loss of bone mineral density due to antiestrogenic therapies. The slow-growing behavior of BML suggests that these tumors can be left untreated unless the patient becomes symptomatic.

CONCLUSIONS

BML is characterized by the presence of single or multiple nodules in the lung. Pulmonary BML has been mainly associated with uterine leiomyomas. Pathologically, BML may resemble lung hamartoma (the most common benign lung tumor), low-grade leiomyosarcoma, or smooth muscle cell proliferation. Pulmonary BML is usually asymptomatic but in some cases presents with minor respiratory symptoms. Most BML cases present with multiple pulmonary tumors after myomectomy and hysterectomy. BML lesions are found predominantly in premenopausal women and express estrogen and progesterone receptors, suggesting a role of these hormones in disease pathogenesis[111] and distinguishing these lesions from other similar-appearing lung nodules. Other diseases that may be confused with BML include pulmonary nodules (e.g., primary leiomyoma, primary leiomyosarcoma, metastatic leiomyosarcoma, pulmonary hamartoma, leiomyomatous hyperplasia, lymphangioleiomyomatosis). Transbronchial and open lung biopsies have been used to diagnose and confirm BML. Pharmacologic or surgical methods that decrease estrogen in patients with BML can result in total regression, but recurrence has been reported; therefore, continued monitoring of patients is advised.

CHAPTER 63

Depositional Lung Disorders: Amyloidosis, Pulmonary Calcification, and Pulmonary Ossification

Robert J. Homer
Christopher Gange
Natalia Neparidze

INTRODUCTION

Deposits of endogenous body constituents or exogenous materials in amounts sufficient to deform structure and impair function can occur virtually anywhere in the body. Deposits of endogenous materials in the lungs or airways cause a variety of diseases (Table 63-1). These may have different clinical manifestations depending on location (i.e., pulmonary parenchyma or conducting airways). This chapter deals with two of these manifestations: amyloidosis and diffuse pulmonary calcification and its variants. Others depositional diseases are discussed elsewhere in this text.

AMYLOIDOSIS

Amyloidosis refers to the extracellular deposition of amyloid, a fibrillar, proteinaceous, insoluble material that has characteristic light, ultrastructural, and histochemical features[1,2] (Fig. 63-1). Electron microscopic examination of amyloid reveals a dominant (95%) fibrillar component with distinctive periodicity, associated with a lesser (5%) pentagonal doughnut-shaped glycoprotein component, physically and chemically identical in all forms of amyloid, which is derived from a soluble plasma protein, soluble amyloid P protein (SAP). Amyloid also includes various glycosaminoglycans, for example, heparan sulfate and certain apolipoproteins (E and J).[3] Radiographic diffraction studies of amyloid show the fibrils to be arrayed in a β-pleated sheet configuration. This accounts for the ordered binding of the histochemical stain Congo red such that Congo red–stained amyloid appears apple-green under polarized light. When amyloid is deposited in tissues it may produce a wide variety of clinical manifestations mediated by atrophy of parenchymal cells (e.g., glomeruli), interference with mechanical function (e.g., heart and lungs), or impaired vasoconstriction of blood vessels, leading to hemorrhage (e.g., lungs and gastrointestinal tract). Mechanisms of tissue injury include direct tissue toxicity and activation of the unfolded protein response.[4] Deposition may occur in multiple organs as a systemic disease or may be limited to a single organ. As a result, classification includes both the specific moiety involved and the clinical syndrome.

TABLE 63-1 Depositional Diseases of the Lungs

Biologic Material	Disease
Interstitial deposition	
Amyloid	Amyloidosis
Water	Interstitial edema
Calcium	Calcification and ossification
Alveolar deposition	
Surfactant	Alveolar proteinosis
Water	Alveolar edema
Calcium	Alveolar microlithiasis
Blood and hemosiderin	Alveolar hemorrhage syndromes

While the main fibrillar component of amyloid can be derived from any one of many potential precursor proteins, only a few are common in disease involving the lung, including immunoglobulin light-chain, serum amyloid–associated (SAA) protein (an acute phase reactant), transthyretin (TTR, a prealbumin molecule made in the liver that binds and transports thyroxine and retinol), and β_2-microglobulin, a component of the major histocompatibility complex (MHC) class I molecule.[5,6] The established amyloid fibril nomenclature is based on the chemical nature of the fibril protein, where an A, for amyloid, is followed by a suffix that is an abbreviated form of the parent or precursor protein. These forms of amyloidosis are therefore known as AL, AA, ATTR, and Aβ_2M, respectively. Generation and deposition of these proteins into amyloid depends on increased production or reduced clearance of the precursor protein, as well as factors enhancing abnormal folding, such as inherited mutations within the precursor protein.[1] An entity related to amyloidosis is light-chain deposition disease (LCDD), in which tissue deposits are also derived from immunoglobulin light chains and are similar to amyloid by routine light microscopy but show granular deposition by electron microscopy rather than fibrils, do not include amyloid cofactors, and do not stain with Congo red.[7] It seems likely that the biochemical properties of the light chain determine the nature of the deposit produced. Finally, there is a third form of immunoglobulin depositional disease, crystal storing histiocytosis (CSH), in which the immunoglobulin forms crystals with an associated histiocytic response. CHS is associated with a range of lymphoproliferative diseases and can also form mass lesions in the lung.[8]

Systemic AL amyloidosis occurs in association with a neoplastic clonal proliferation of B cells or plasma cells that produce a monoclonal immunoglobulin or immunoglobulin fragment (monoclonal gammopathy). In most cases, the neoplastic clone may clinically manifest as multiple myeloma or lymphoma (generally lymphoplasmacytic lymphoma or other low-grade non-Hodgkin's lymphoma) or may be subclinical (formerly known as primary amyloidosis), causing bone-marrow plasmacytosis. Most often the protein source is a λ-light chain, either intact or the amino terminal fragment. Systemic AL amyloidosis can present with a variety of symptoms or signs including fatigue and weight loss, heavy proteinuria and/or nephrotic syndrome, hepatosplenomegaly, otherwise unexplained heart failure, muscle (including tongue) enlargement, waxy skin, bleeding, and neuropathy (including carpal tunnel syndrome).

AA amyloidosis can occur as a complication of any long-term inflammatory disorder.[9] It was formerly seen predominantly in patients with chronic infections (e.g., tuberculosis, leprosy, and chronic osteomyelitis) but is now seen more commonly with noninfectious chronic inflammatory diseases (e.g., rheumatoid arthritis, familial Mediterranean fever, or Crohn's disease). Rarely, it may be due to neoplasms or is idiopathic.[9] The precursor in most cases is encoded by the SAA1 gene, with rare cases of SAA2 also described. Allelic variants of SAA1 that are associated with propensity to self-aggregate increase the risk of AA. SAA is made predominantly

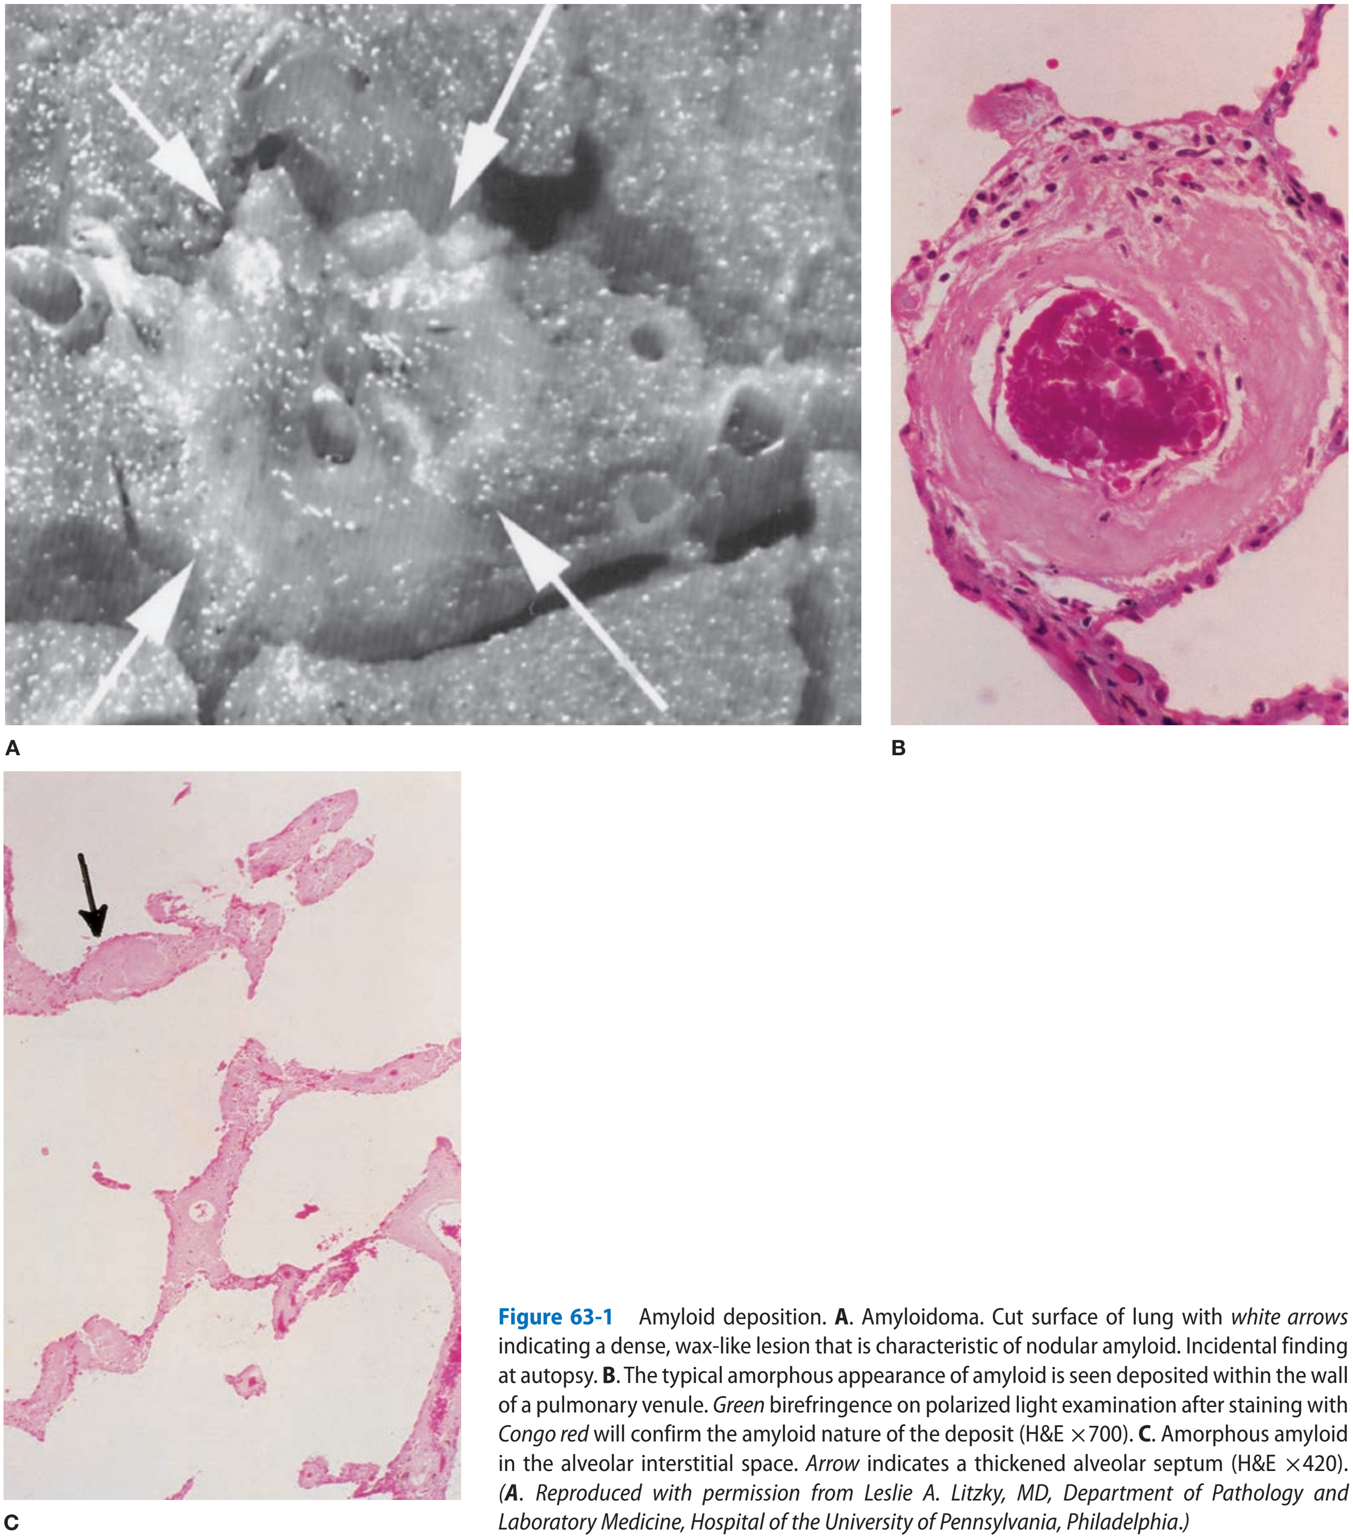

Figure 63-1 Amyloid deposition. **A**. Amyloidoma. Cut surface of lung with *white arrows* indicating a dense, wax-like lesion that is characteristic of nodular amyloid. Incidental finding at autopsy. **B**. The typical amorphous appearance of amyloid is seen deposited within the wall of a pulmonary venule. *Green* birefringence on polarized light examination after staining with *Congo red* will confirm the amyloid nature of the deposit (H&E ×700). **C**. Amorphous amyloid in the alveolar interstitial space. *Arrow* indicates a thickened alveolar septum (H&E ×420). *(**A**. Reproduced with permission from Leslie A. Litzky, MD, Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, Philadelphia.)*

by the liver but is also made by other cells such as macrophages, endothelial cells, and smooth muscle under control of proinflammatory cytokines such as tumor necrosis factor, interleukin 1 beta, and interleukin 6. Systemic AA almost always presents with renal disease as proteinuria and/or nephrotic syndrome.

TTR is deposited in familial amyloid polyneuropathies in which there is a germline TTR mutation that encourages amyloid formation (referred to either as *ATTRv* for variant or *ATTRm* for mutant) and systemic wild-type ATTR (sometimes called *ATTRwt*) amyloidosis. The latter is also referred to as *systemic senile amyloidosis* as it is relatively common in an elderly population, although there is clinical overlap with the mutant form. Patients commonly show cardiomegaly and heart failure. Carpal tunnel syndrome also is common, as is spinal stenosis. Untreated patients with ATTRwt survive longer than patients with AL with equivalent amounts of cardiac involvement.[10] TTR-related amyloid can also be observed as an incidental finding in the heart at autopsy.

β_2-microglobulin deposition (Aβ_2M amyloidosis) is seen in patients with chronic renal failure on dialysis.[11] Patients with dialysis-related amyloidosis most commonly complain of shoulder pain, related to scapulohumeral periarthritis and rotator cuff infiltration by amyloid, and of symptoms of carpal tunnel syndrome.

Pulmonary Involvement in Amyloidosis

Amyloidosis involving the lung is usually a manifestation of multiorgan disease, while disease localized to the lung in absence of systemic disease is much less common.[6,12] Pulmonary-specific manifestations include dyspnea and dry cough with an interstitial radiographic pattern, nodules (amyloidomas), and rarely pulmonary hypertension. Several radiotracers have proved useful in detecting amyloidosis. The radiotracer used in routine bone scintigraphy, Tc-99m hydroxymethylene diphosphonate (HDP), is taken up specifically by transthyretin amyloid deposits and can be used in cardiac imaging to identify this type of amyloid deposit.[13,14] PET radiotracers initially developed for use in brain imaging for Alzheimer's disease are also taken up by light chain and transthyretin amyloid and are being investigated for cardiac and systemic uses.[15,16]

Tracheobronchial infiltration can cause hoarseness, stridor, airway obstruction, and dysphagia. In addition to pulmonary involvement per se, amyloidosis may also cause respiratory symptoms due to deposition in any portion of the respiratory tract or in other organs. For example, deposits in the tongue may be extensive enough to cause obstructive sleep apnea. Persistent pleural effusions may be due to both pleural and cardiac disease. Diaphragmatic deposition may lead to respiratory failure. Pulmonary involvement is most commonly due to AL (about 80%) followed by ATTR (both hereditary and wild type), AA, and Aβ2M.[6,17] Most patients can be characterized as having tracheobronchial amyloidosis, nodular parenchymal amyloidosis, or diffuse septal amyloidosis.[12] Tracheobronchial amyloid deposition and nodular parenchymal amyloid deposition (amyloidoma) **(Fig. 63-1A)** most often occur as isolated local phenomena, whereas diffuse interstitial deposition is most often seen in systemic amyloidosis.

Nodular Parenchymal Amyloidosis

Solitary amyloid nodules (amyloidomas) are commonly incidental radiographic findings in asymptomatic individuals although there is an increase in patients with Sjögren syndrome **(Fig. 63-1A)**.[5,12,18] These nodules have no distinctive imaging features on radiograph or CT and may be soft tissue attenuation, partially calcified, or rarely cavitary. Noncalcified amyloidomas are reported to have low signal intensity on T2 and are isointense to skeletal muscle on T1-weighted imaging, but due to the limitations of MR for evaluating lung nodules this is rarely performed clinically.[19] While the diagnosis of an amyloid nodule is typically made after surgical resection, it is possible to make the diagnosis on transbronchial biopsy or core needle biopsy.[20] However, surgical excision of one or more nodules may sometimes be prudent, since, on rare occasion, amyloid deposition occurs within a pulmonary neoplasm (e.g., a primary pulmonary neoplasm such as a typical carcinoid or a metastatic neoplasm such as medullary carcinoma from the thyroid). It is possible that advances in biochemical analysis of the amyloid (see below) may influence this decision, but this is not yet commonly discussed in the literature.

Nodular parenchymal amyloidosis is most often said to represent AL. However, one study showed that the deposits are a mixture of light and heavy chains, which is rare in most cases of systemic AL.[12] Histologically, the amyloid deposit is often associated with an intense inflammatory reaction consisting of plasma cells, macrophages, and multinucleated giant cells. While a clonal population of plasma cells and/or B cells can be identified in many cases—and in a few instances, nodular amyloidosis has been associated with a histologically apparent low-grade pulmonary lymphoma—clinical follow-up of nodular parenchymal amyloidosis unassociated with systemic disease is generally benign. It has been suggested therefore that in cases of AL limited to the lung, as shown by appropriate investigations such as liver function tests, renal function tests, and echocardiography, only a limited search for an occult lymphoproliferative disorder need be undertaken.[12,21] Rare cases of systemic AL, localized AA, localized ATTRwt, and localized Ab$_2$M/AL also have been reported to present as nodular amyloidosis.[6,22]

Tracheobronchial Amyloidosis

Amyloid deposition in the tracheobronchial tree can produce either plaques or tumoral masses.[23–25] Like nodular amyloid, this usually represents AL, but a clonal source is rarely found, and the material commonly has a polytypic mix of immunoglobulin light and heavy chains.[12] The more common presentation as plaques is diffuse and multifocal and represents submucosal deposition of amyloid. Diffuse or proximal involvement of the airways is apt to be symptomatic, producing cough, stridor, or hemoptysis. Less commonly, deposition of amyloid in the tracheobronchial tree produces a solitary mass, which mimics an endobronchial neoplasm with signs of bronchial obstruction or hemorrhage. Both types of airways lesions can be readily identified by bronchoscopic examination. However, as is the case with amyloid deposition at all sites, with biopsy there is a risk of hemorrhage. Although localized tumoral masses may be treated by excision or observation, more diffuse involvement may be treated by laser ablation, stents, or radiation. Involvement of proximal airway leads to significant mortality, while involvement of distal or mid airway has generally good prognosis.

Diffuse Interstitial Amyloidosis

Widespread, diffuse interstitial amyloidosis of the pulmonary parenchyma may produce either a reticulonodular or miliary pattern on the chest radiograph and CT and may result in confluent consolidations with a basilar and peripheral distribution.[5,26] The deposition of amyloid may involve the alveolar septal interstitium, the walls of small blood vessels, or both **(Fig. 63-1B, C)**. Such pulmonary involvement occurs most often in patients with systemic amyloidosis, derived from either immunoglobulin light-chain or AA protein and is only rarely localized.[5,6,27] Pulmonary interstitial amyloid deposition in secondary involvement is rarely sufficiently severe to produce clinical manifestations and is most commonly diagnosed at autopsy. Uncommonly, it may produce progressive dyspnea, hemoptysis, or restrictive pulmonary function tests. It is thought that the morbidity and mortality of diffuse septal amyloidosis in patients with systemic disease is related to concurrent cardiac amyloidosis with which tissue burden closely correlates, possibly explaining why septal amyloidosis by itself in this setting is not of more significance. On the other hand, primary diffuse interstitial pulmonary amyloidosis has been considered to have a relatively poor prognosis.

Diagnosis and Treatment of Amyloidosis

Pathologic diagnosis of amyloidosis requires tissue examination with concurrent Congo-red or equivalent amyloid-specific staining and/or electron microscopy. In cases of systemic amyloidosis, clinically uninvolved sites allow less invasive sites to be biopsied with reasonable expectation of a positive result. The classic fat pad biopsy has a sensitivity of between 60% and 85% in experienced hands.[28,29] It is important that both the aspiration and the sample processing be done by those with experience in the technique. However, this procedure has low sensitivity in patients with single organ involvement.

It is essential that the biochemical nature of the amyloid protein be established since this cannot be predicted from clinical manifestations alone. Even in patients with a known plasma cell dyscrasia, if amyloid is detected, it should not be assumed that this represents AL amyloid, since a significant number of patients with familial or senile type amyloid also have plasma cell dyscrasias. Historically, a variety of immunohistochemical and immunofluorescence tests were used, combined with genetic testing; but these commonly required frozen tissue, which were technically challenging and did not always provide an answer. More recently, improved immunohistochemistry and biochemical techniques have become available and are applicable in formalin-fixed paraffin-embedded tissue.[30] These techniques, especially mass spectroscopy, allow specific identification of the associated amyloid precursor protein including any possible genetic variants. Published data show these approaches are highly robust and generalizable to multiple clinical scenarios, although they have not yet been reported in patients with isolated pulmonary disease.

While it is beyond the scope of this chapter to discuss therapy in depth, it is important to note that therapy for systemic disease is highly dependent on the specific peptide responsible. For systemic light chain–associated amyloidosis, complete evaluation for nature of an underlying B cell or plasma cell malignancy should be conducted. Staging, including assessment for cardiac involvement, is a critical determinant of overall survival.[31] Hence, thorough cardiac assessment with combination of cardiac markers (N-terminal pro B-type natriuretic peptide [NT-proBNP], troponin levels), as well as imaging with echocardiogram and cardiac magnetic resonance, provide crucial prognostic information.

In cases of systemic AL amyloidosis, there has been considerable progress in treatment with introduction of myeloma-type therapy. For eligible patients, high-dose prednisone and melphalan therapy combined with use of hematopoietic stem-cell transplantation is effective.[31] Newer agents, such as thalidomide, lenalidomide, and related compounds—especially bortezomib, which targets plasma cells—have revolutionized the field. Bortezomib has been the backbone treatment, in combination with cyclophosphamide and dexamethasone (CyBorD); remarkable overall hematologic response rates have been noted. Novel biologic agents targeting plasma cells, such as daratumumab, which targets CD38, also represent a significant breakthrough in therapy. The combination of daratumumab plus bortezomib is emerging as a novel standard of care in systemic AL amyloidosis.[31] Finally, efforts are ongoing to target and eradicate amyloid deposits through monoclonal antibodies directed at specific epitopes of light chain amyloid fibrils, although results have not been positive to date.[31]

In contrast, treatment for AA amyloidosis focuses on the underlying inflammatory disease but may also include small molecule inhibitors.[9] Treatment for systemic ATTR (both ATTRv and ATTRwt) has been approached with small interfering RNAs and selective binders to ATTR to prevent amyloidogenesis.[32,33] In some cases, organ (liver, heart) transplantation has been explored. The significance of these therapies for lung-limited disease is unclear, since localized disease is typically treated with ablative therapy such as stents, radiation, laser treatment, resection, and other localized methods. The more recent systemic therapies have only rarely been reported in patients with initial, lung-limited disease.[5]

PULMONARY CALCIFICATION AND OSSIFICATION

Calcification of the pulmonary parenchyma may occur by deposition on normal tissues as metastatic calcification, on abnormal tissues as dystrophic calcification, or, as a special subtype, within alveoli as alveolar microlithiasis.[34–36] *Pulmonary ossification* refers to actual bone tissue formation with or without marrow elements, which is usually but not always secondary to other injury. While other organs can be affected by ectopic calcification and ossification, the lungs are particularly susceptible. Multiple factors contribute to the development of metastatic and dystrophic calcification, including increased serum levels of calcium and phosphate, alkaline phosphatase activity, and local tissue pH.

■ Metastatic and Dystrophic Calcification

Metastatic calcification (Fig. 63-2) typically but not always occurs in association with some derangement of calcium metabolism, such as primary hyperparathyroidism, secondary hyperparathyroidism of chronic renal failure, hypervitaminosis D, the milk-alkali syndrome, sarcoidosis, or increased bone turnover due to multiple myeloma or metastatic carcinoma.[37]

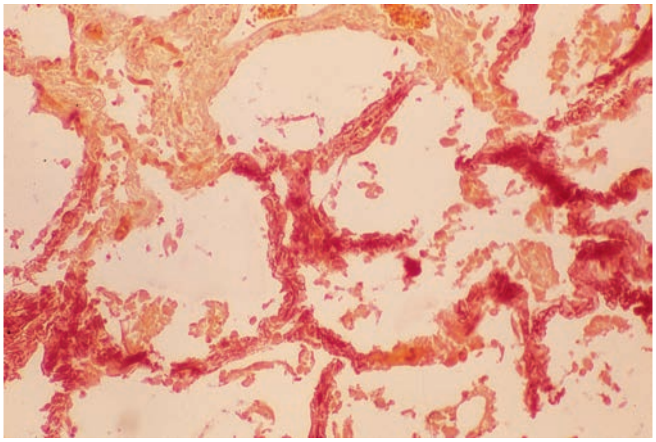

Figure 63-2 Metastatic calcification of alveolar septa in a renal dialysis patient. Photomicrograph shows calcium forming a *dark red* precipitate within the alveolar septa (Alizarin red ×280).

Although metastatic calcification can occur in almost any tissue of the body, it occurs most often in the lungs, kidneys, and the stomach (tissues with more alkaline pH), as well as the walls of blood vessels. Metastatic calcification in the lungs usually affects the interstitium of the alveolar septa and the walls of bronchioles and pulmonary vessels, sometimes localizing on elastic fibers.

On chest radiograph, metastatic calcification often appears as a patchy opacity, and calcifications in the lungs may be visible; however, mild cases may also result in a normal study.[38] These opacities may be confluent and mimic pneumonia but will persist on subsequent studies after antibiotic treatment, warranting a chest CT. Although the calcific nature of the opacity may be apparent on routine chest radiograph, a chest CT is more sensitive both in detecting interstitial deposits and in demonstrating calcification. Moreover, a CT scan may also demonstrate calcification of chest wall blood vessels, circumstantially implicating calcification as the cause of pulmonary parenchymal abnormalities.[39] Nuclear medicine studies can also be used to evaluate calcified opacities, as these deposits will show increased uptake of bone scan agents such as ^{99m}Tc-MDP and ^{18}F-NaF.[40,41]

Clinical manifestations of diffuse pulmonary metastatic calcification are unusual, occurring most often in patients who are in chronic renal failure, particularly in those on chronic hemodialysis. Only rarely do patients manifest dyspnea or arterial hypoxemia, and pulmonary function tests tend not to show signs of restrictive pulmonary disease. Unexplained dyspnea in a patient with chronic renal failure or hypercalcemia in the presence of a normal chest radiograph should lead to consideration of high-resolution computed tomography (HRCT). Rarely, respiratory failure may develop, although death from metastatic calcification is typically due to cardiac disease.

The mechanism responsible for metastatic pulmonary calcification is unknown. Although high levels of parathyroid hormone or a marked increase in the calcium-phosphate solubility product occur in some patients, diffuse calcification can occur in the absence of either. The presence and severity of metastatic calcification correlates poorly with serum calcium and phosphorus levels, degree of parathyroid hyperplasia or activity, type of primary disease, or length of dialysis. Ultrastructural observations of minimal, presumably early, lesions show selective deposition of calcium on elastic fibers, suggesting that they may serve as the initial nidus.

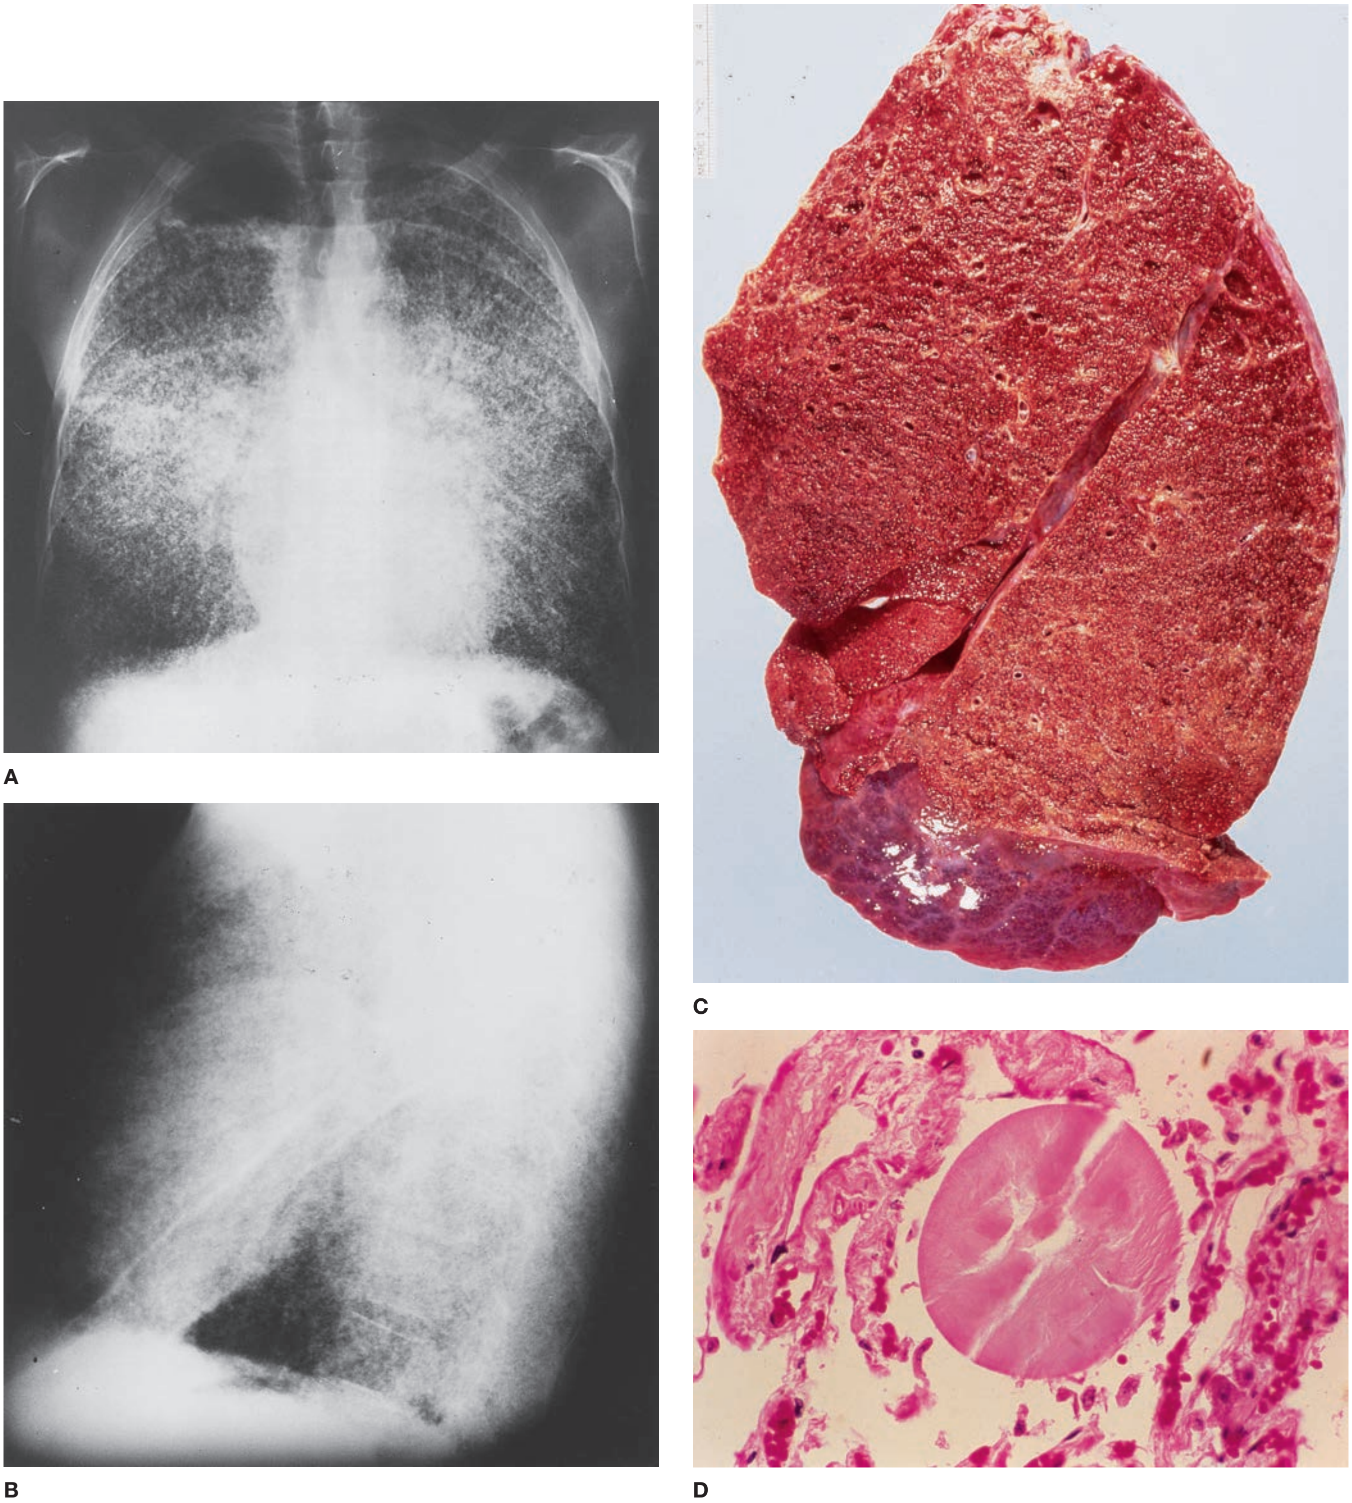

Figure 63-3 Alveolar microlithiasis in a 46-year-old man admitted for nonpulmonary problems. History included slight dyspnea on exertion and previous episodes of "pneumonia" in 1947, 1950, and 1952. Clinical examination revealed severe restrictive lung disease, pulmonary hypertension, and cor pulmonale. Diagnosis confirmed by lung biopsy. **A** and **B**. Posterior–anterior and lateral chest radiographs demonstrate innumerable, tiny calcified nodules throughout both lung fields. Thin, lucent lines on each side represent normal pleura visualized between the calcified pulmonary parenchyma and the chest wall. Emphysematous blebs in the apices displace the calcifications. **C**. Cut surface of explanted lung from a patient undergoing lung transplantation for primary alveolar microlithiasis. Note the fine nodularity that correlated with the chest radiographs. **D**. Photomicrograph demonstrating a typical calcospherite in an alveolar space (H&E ×1120). *(**C**. Reproduced with permission from Leslie A. Litzky, MD, Department of Pathology and Laboratory Medicine, Hospital of the University of Pennsylvania, Philadelphia.)*

In metastatic calcification, specific conditions that elevate the calcium-phosphate product should be corrected to prevent further calcification. Renal transplantation for patients with end-stage kidney disease often mitigates this process. In some cases, however, the calcification persists and progresses even with a functioning transplanted organ; some of these cases may be due to tertiary hyperparathyroidism. In such severe cases, parathyroidectomy may be indicated. Spontaneous resolution of MPC also has been described, although it is rare.

In contrast to metastatic calcification, dystrophic calcification, typically consisting of hydroxyapatite, occurs in injured tissue (such as within the granulomas of tuberculosis or sarcoidosis), pulmonary hypertension, other postinfectious conditions, amyloidosis, malignancies, or pneumoconiosis. This type of calcification is usually localized; its distinctive radiographic features are sometimes diagnostically helpful. It is rarely of any clinical significance beyond that of the underlying condition. Histologic variants of other calcium-containing endogenous mineral deposits, including blue bodies and myelin lamellar type bodies, also have been described.[35] These are of no known clinical significance.

■ Pulmonary Ossification

Pulmonary ossification, in contrast to calcification, refers to the formation of mature bone tissue, often with marrow elements, within the lungs. It may occur on the background of dystrophic calcification. This may be observed in chronic necrosis or in slowly growing tumor masses, particularly metastatic colonic adenocarcinoma or tumors such as metastatic osteosarcoma that produce bone.[35,42]

Pulmonary ossification can be subdivided into two histologic forms, both of which may be found in the same patient: nodular and branching (also known as dendriform) ossification. Nodular ossification is characterized by lobulated bone nodules within alveolar spaces, usually devoid of fat or marrow elements. The nodular circumscribed form of pulmonary ossification consists of small nodules, 2 to 8 mm in maximum dimension. Nodular ossification usually develops in the setting of passive congestion and pulmonary edema, as from chronic heart failure or cardiac valvular abnormalities.

Dendriform ossification in the lungs is characterized by formation of branching bone tissue that often contains marrow elements. It preferentially affects the alveolar interstitium and extends through alveolar septae. Dendriform ossification is often associated with underlying fibrotic lung disease, chronic inflammation, or sequelae of acute respiratory distress syndrome but can also be idiopathic.[42,43] Chest radiograph demonstrates coarse reticular opacities in the lower lung zones. HRCT demonstrates linear 1- to 5-mm calcific densities with high-density nodules associated with reticulations in a subpleural and basilar distribution.[44,45]

■ Pulmonary Alveolar Microlithiasis

Pulmonary alveolar microlithiasis (PAM) is a rare autosomal recessive disorder characterized by intra-alveolar accumulation of calcified concretions, commonly referred to as microliths, in the absence of any known calcium metabolism disorder.[36] It can be considered a specialized form of calcification involving alveolar spaces. This disorder usually is found incidentally with an abnormal chest radiograph in an asymptomatic patient (Fig. 63-3). Presentation may occur at any age, although symptoms usually occur in the third or fourth decade of life. Diagnosis is made on the basis of the chest radiograph or HRCT showing diffuse opacities with calcifications throughout the lungs plus genetic testing.[46] HRCT findings include linear subpleural calcifications that progress to large confluent calcifications with a lower lobe predominance. Although not usually required, bronchoalveolar lavage or biopsy also may confirm the diagnosis. Biopsy shows calcified spherules filling alveolar spaces (Fig. 63-3).

There are radiographic stages of severity ranging from few microliths and minimal calcification to extensive calcification, including of pleura, resembling a "white-out." Although usually asymptomatic at the time of presentation, alveolar microlithiasis typically progresses to end-stage lung disease; the rate of progression is highly variable. When end-stage lung disease occurs, the findings are those of restrictive pulmonary disease or exercise-induced pulmonary hypertension. No therapy has proved effective, but lung transplantation has been performed successfully in a few patients.[47]

The disease is due to a mutation in a type IIb sodium-phosphate cotransporter (SLC34A2) gene. As surfactant phospholipids are metabolized, phosphate is liberated, and the transporter is needed to eliminate the excess phosphate from the alveolar space. In the absence of this transporter, increased phosphate levels lead to microlith formation. While this is most dramatic in the lungs, many other organs, for example, kidney, stomach, prostate, also can be affected. The accumulation of microliths ultimately leads to loss of vital capacity by mass effect as well as by inducing underlying parenchymal fibrosis.

CHAPTER 64

Pulmonary Toxicity Related to Systemic Treatments for Cancer

Jennifer D. Possick
Erin DeBiasi
Lynn T. Tanoue

INTRODUCTION

Toxicities related to medications constitute a major category of iatrogenic illness. All agents used for cancer treatment have the potential to cause toxicity. As with every medical intervention, the risks of treatment may be acceptable if they are outweighed by the potential benefit of longer survival or cure of disease. It is essential that the patient be engaged in a discussion of this balance before embarking on treatment.

Over the past decade, the landscape of oncologic therapeutics has witnessed enormous advances, with scientific discovery driving substantial and innovative change. The emergence of molecularly targeted treatments and immunotherapy has fundamentally changed both front-line and secondary approaches for a multitude of cancers, enhancing precision and personalization of therapy. The success of new treatments inevitably will be tempered by a new array of associated pulmonary complications, the extent and severity of which may not be completely elucidated in clinical trials. We are very much still in the learning curve of recognizing and addressing related toxicities of novel therapeutics. Moreover, cancer treatments often carry the additional complexity of combination approaches with other drugs or radiation, concomitant hematopoietic support, or bone marrow or stem cell transplantation. Further, as advances in therapeutics result in improved long-term survival, cancer is becoming a chronic disease for a growing number of patients. The potential for delayed complications adds additional challenge to the evaluation of pulmonary complaints in cancer survivors.

As knowledge of biologic mechanisms fundamental to neoplasia burgeons, the horizon for treatment approaches will continue to expand, and inevitably so will the spectrum of associated pulmonary complications. Consequently, the pulmonologist must maintain a sharp awareness of the potential for treatment-related toxicities in both short- and long-term oncologic settings. This chapter reviews the evaluation of patients with suspected therapy-induced pulmonary toxicity and the potential toxicities associated with specific classes of systemic treatment.

APPROACH TO THE PATIENT WITH SUSPECTED PULMONARY TOXICITY RELATED TO SYSTEMIC TREATMENT FOR CANCER

General clinical principles related to, and pulmonary function testing and diagnostic evaluation of, patients with suspected pulmonary toxicity due to systemic therapy for cancer are discussed below.

General Principles

The evaluation of patients with cancer who develop pulmonary complications while receiving treatment is often challenging, as the diagnosis of drug-induced pulmonary toxicity is typically one of exclusion. The possibility of adverse effects of therapy must be considered within the complex medical context inherent to an individual patient undergoing physically challenging and often immunosuppressing treatment. Patients most often present with nonspecific constitutional or respiratory complaints. In many cases, symptoms and physical signs may be minimal or even absent. In these situations, the only evidence of an ongoing pulmonary process may be an abnormal chest radiograph or computed tomography (CT) scan. Even when clinical symptoms and imaging abnormalities are present and severe, they are usually nonspecific. Reasonable certainty that the patient's clinical complaints and radiographic changes represent treatment toxicity is critical, as changing a therapeutic regimen may affect the chance for prolongation of survival or cure. It is important to recognize several complicating features inherent to the oncology patient population.

- First, treatment may be given in multidrug regimens or in combination with other modalities such as radiation therapy, bone marrow transplantation, or stem cell transplantation. Assigning pulmonary toxicity to a single drug or modality within such a regimen is often impossible, as experience and published literature relevant to complications of combination therapies may be scant. Moreover, the combined toxicity of two or more drugs or a single drug with radiation therapy may exceed the individual toxicities of those drugs.
- Second, patients undergoing chemotherapy are often immunosuppressed, either from the malignancy itself or from myelosuppressive or immunologic effects of their treatment. These patients are, therefore, susceptible to both usual and opportunistic infection, which may be indistinguishable radiographically from treatment toxicity. Recognizing that the lung is the most common site of serious infection in immunocompromised patients, it is important to remember that infection is still the most likely culprit when pulmonary symptoms and radiographic abnormalities occur.
- Third, cancers themselves may mimic lung disease. This is particularly true in cases of lymphangitic tumor spread or metastases to the lung parenchyma or pleura.
- Fourth, toxicity from some drugs appears to be related to cumulative dosage levels. However, adverse reactions may occur even with a low total dose, when clinical suspicion for toxicity is low.
- Finally, pulmonary toxicity due to a single therapeutic agent may present with several different syndromes that vary clinically, radiographically, and temporally. While a severe pulmonary reaction acutely following treatment administration usually raises suspicion of drug toxicity, toxicity due to some agents may be delayed by months to even years after treatment.

Pulmonary Physiologic Testing

Pulmonary physiologic testing is commonly utilized in surveillance of patients receiving treatments with potential for pulmonary toxicity. A multitude of investigations studying the utility of pulmonary function testing (PFT) in monitoring pulmonary effects related to administration of cancer therapeutic agents, particularly chemotherapy and immunotherapy, have been reported, but the reliability of application of these findings to clinical management has not been rigorously studied.

Various physiologic abnormalities in the context of cancer treatments have been described, the most common of which are decreases in lung volumes and diffusing capacity for carbon monoxide (DL_{CO}). Patients receiving chemotherapy who are monitored serially by PFT frequently demonstrate physiologic abnormalities in the absence of clinical signs of toxicity, with abnormalities in DL_{CO} in particular thought by some to be indicative of early-onset, drug-related pulmonary injury.[1–3] Discontinuation of drug in this setting, with or without initiation of treatment such as corticosteroids, typically results in improvement. Whether early intervention based on DL_{CO} abnormalities in the absence of clinical symptoms decreases the likelihood of long-term pulmonary impairment is unclear. In situations of clinically evident drug toxicity accompanied by PFT abnormalities, withdrawal of culprit therapy may not be accompanied by improvement in physiologic measurements. For example, in a study examining pulmonary function in 116 long-term (5–13 years after treatment) survivors of Hodgkin disease in Norway, nearly 30% of patients had exertional dyspnea with associated pulmonary function abnormalities.[4] Multivariate analysis of these patients identified chemotherapy with a combination of bleomycin and anthracyclines as the sole significant predictor of lung function impairment.

A number of factors further complicate the practice and interpretation of PFT in the oncology population. Many PFT physiologic parameters are effort dependent. The ability of a patient to consistently perform test maneuvers may be affected by weakness, pain, or the use of analgesic medications. Reproducibility of results, therefore, may be a significant barrier in patients whose functional status and strength are impaired by the effects of their cancer or its treatment. Many patients have anemia induced by malignancy, medication, or chronic illness. Since DL_{CO} is affected by hemoglobin concentration, it is necessary that appropriate corrections for anemia be made. Oncology patients may also be subject to processes other than drug toxicity that will affect PFT results. Primary pulmonary malignancy, metastatic lung disease, infection, thoracic or abdominal surgical procedures, and a host of other clinical situations may all independently cause variation in physiologic measurements. Therefore, identifying pulmonary physiologic abnormalities specific to treatment may prove very difficult. Moreover, in all patients in whom therapy-related toxicity is a concern, consideration must be given to the possibility that discontinuation of a specific treatment might result in substitution of less effective therapy.

Ultimately, even though the predictive value of baseline or serial PFT remains unclear, most clinicians will continue to rely on such testing as a screening and monitoring tool. Although there are no definitive data that toxicity can be averted by such monitoring, we are limited by the absence of other means of identifying toxicity early enough to prevent severe pulmonary disease. Although the presence of subclinical abnormalities does not imply that patients will develop irreversible lung disease, such abnormalities may dictate closer monitoring, or even withdrawal of drug. Conversely, normal physiologic testing cannot predict abrupt toxicity that may produce profound pulmonary injury. As always, medical decisions based on pulmonary physiologic findings must be made in the context of the patient's overall clinical situation.

■ Diagnostic Evaluation

Given the potential impact of treatment-related pulmonary toxicity on a patient's present and future cancer treatment, it is important to establish this diagnosis as firmly as possible. Thoughtful and judicious use of invasive procedures plays an important role in that evaluation.

The approach to the cancer patient in whom pulmonary injury related to treatment is suspected should parallel the approach to any immunocompromised patient with diffuse or localized lung disease. Because clinical features are usually not specific, sampling of respiratory tract secretions and/or lung tissue may be critical to this evaluation. Direct sputum examination or culture may suggest specific pathogens or may be diagnostic of infections such as *Pneumocystis jiroveci* pneumonia, nocardiosis, or tuberculosis. In the absence of diagnostic sputum findings, invasive procedures may be necessary. Transthoracic needle aspiration of the lung may be useful with focal lesions, although the utility of this type of biopsy in diffuse lung disease is relatively low. This is particularly problematic for patients with drug-induced pulmonary toxicity, which often presents with a diffuse interstitial pattern on chest imaging. Fiberoptic bronchoscopy with bronchoalveolar lavage and transbronchial biopsy has become central to the evaluation of both diffuse and localized lung disease in the immunocompromised host. Bronchoscopy is associated with a low rate of major complications. Diagnostic yield varies widely, reflecting the broad range of disease processes that can involve the lung in the immunocompromised patient. Highest diagnostic yields are obtained in patients with infections or when the causative issue is the malignancy itself; lower yields are seen in interstitial inflammatory processes, which may include toxicity from treatment. However, even in situations in which a specific etiology is not identified, exclusion of infection or malignancy by bronchoscopy often provides clinically useful information. If other interventions and procedures are nondiagnostic, surgical biopsy may be indicated. Thoracoscopic or open lung biopsy is associated with the highest diagnostic yield and can be performed with low complication rates even in critically ill patients.

PULMONARY TOXICITIES ASSOCIATED WITH CHEMOTHERAPEUTIC AGENTS

Older studies suggest that 5% to 10% of patients undergoing chemotherapy ultimately develop therapy-related pulmonary complications.[5–7] It would be impossible to list every chemotherapeutic agent and its associated possible pulmonary toxicities. Moreover, any drug can cause an idiosyncratic reaction in an individual patient. Nonetheless, recognition of the typical patterns of pulmonary adverse reactions that can occur with such agents is an important body of knowledge for pulmonologists. This section will review the major classes of chemotherapeutic drugs used for cancer treatment and their most common pulmonary toxicities.

■ Cytotoxic Antibiotics

A variety of cytotoxic antibiotics have been associated with pulmonary toxicity; the most common of these are bleomycin, mitomycin C, and actinomycin D (Table 64-1).

Bleomycin

Bleomycin, a cytotoxic antibiotic produced by *Streptomyces verticillus*, is used in the treatment of various malignancies, including lymphomas, germ cell tumors, and squamous cell cancers of the head and neck. Lung tissue appears to be particularly susceptible to bleomycin-induced injury because of a relative lack of the inactivating enzyme bleomycin hydrolase.[8] The most severe pulmonary complication is interstitial pneumonitis progressing to fibrosis and respiratory failure; less severe syndromes include organizing pneumonia and hypersensitivity pneumonitis.[9]

Bleomycin-induced pulmonary injury is well described in animal models used for the study of pulmonary fibrosis. Endothelial injury via oxidative stress is the sentinel event, followed by the influx of inflammatory cells (predominantly macrophages, neutrophils, and lymphocytes), development of perivascular edema, elaboration of inflammatory cytokines, and, ultimately, fibroblast activation and fibrosis (Fig. 64-1).[10] A variety of mediators have been implicated in bleomycin-induced lung injury, including tumor necrosis factor α (TNF-α), transforming growth factor β (TGF-β), interleukin 6 (IL-6), and IL-1.[9] Human studies have demonstrated activation of in vitro alveolar macrophages in response to bleomycin, and patients treated with bleomycin for testicular cancer demonstrate a rise in serum TNF-α 3 to 24 h after drug administration.[11,12] The continued expression of TNF-α and IL-1 may predispose to the production of TGF-β and promotion of dysregulated collagen production

TABLE 64-1 Cytotoxic Antibiotics

Drug	Pulmonary Syndromes	Treatment	Comments
Bleomycin	• Chronic pneumonitis • Pulmonary fibrosis • Rare fulminant variant with acute respiratory failure	• Discontinue drug • Corticosteroids	• Risk Factors: Cumulative dose >400 U; supplemental oxygen; therapeutic radiation; renal insufficiency; age >70 years; additional cytotoxic drugs
	• Hypersensitivity-type lung disease	• Discontinue drug • Corticosteroids	• Dyspnea, cough, skin rash, and peripheral eosinophilia
	• Chest pain syndrome	• Discontinue drug	• Associated with drug infusion
Mitomycin-C	• Chronic pneumonitis • Pulmonary fibrosis • Rare fulminant variant after single dose	• Discontinue drug • Corticosteroids	• Risk factors: oxygen therapy; therapeutic radiation, additional cytotoxic drugs
	• Acute dyspnea and/or bronchospasm	• Discontinue drug • Bronchodilators • Supportive care • Consider corticosteroids	• Risk factors: vinca alkaloid use • May develop noncardiogenic pulmonary edema and/or chronic interstitial disease • Can recur with rechallenge with vinca alkaloids alone
	• Hemolytic uremic syndrome	• Discontinue drug • Supportive care • Poor response to plasmapheresis or corticosteroids	• Microangiopathic hemolytic anemia, thrombocytopenia, renal insufficiency, noncardiogenic pulmonary edema • Rare alveolar hemorrhage
Actinomycin-D	• "Radiation recall" pneumonitis	• Discontinue drug	• Radiation recall effect may persist

and fibrosis. Animal studies have shown that bleomycin-induced pulmonary toxicity can be ameliorated or prevented by antibodies to TNF-α and TGF-β, or receptor antagonists to IL-1; knockout of the TNF-α receptor also has demonstrated protective effects.[13–15] Bleomycin also induces direct free-radical damage after oxidation of the bleomycin-Fe (II) complex; this effect has been mitigated by iron depletion with chelators both in vitro and in vivo.[9]

The incidence of bleomycin-induced pneumonitis is reported from 6% to 18%, with overall mortality estimated at 3% or less.[9,16] Several risk factors for severe bleomycin-induced pneumonitis have been identified: (1) Toxicity appears to correlate with higher cumulative dose. While fatal injury has been observed after administration of <100 units, there is a significant escalation in toxicity with total doses >400 units, and severe toxicity develops in 20% of patients receiving >500 units.[17] (2) Exposure to high concentrations of supplemental oxygen, particularly in the setting of general anesthesia, may create synergistic toxicity. This is primarily based on animal data, including a study that demonstrated a 75% increase in mortality in hamsters treated with bleomycin and 70% oxygen for 72 h versus bleomycin alone.[18] Similar observations in humans have been largely anecdotal, but in general high fractions of supplemental oxygen are generally avoided whenever

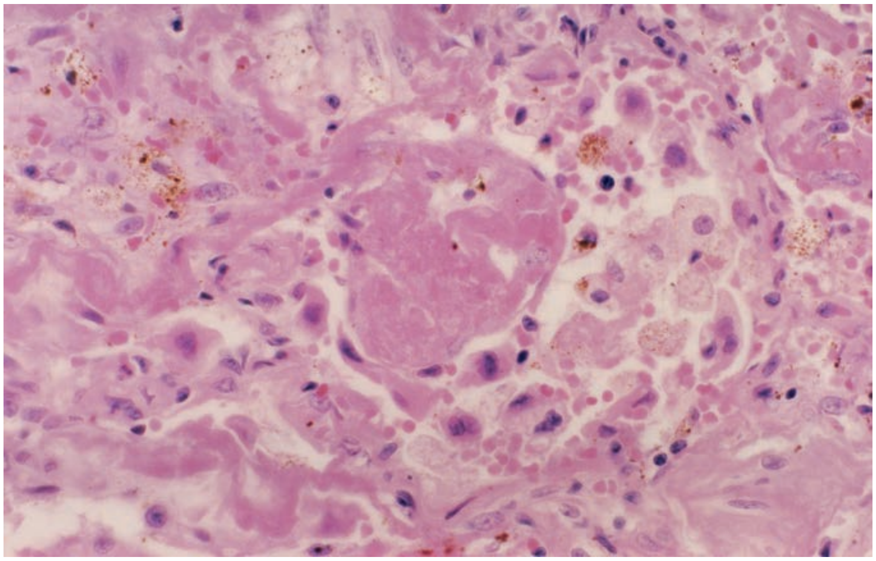

Figure 64-1 Lung biopsy specimen from a patient with clinical and radiographic evidence of bleomycin-induced pulmonary toxicity shows drug effect with acute and chronic changes. The alveolus contains an exudate of fibrin, which is undergoing organization and is surrounded by alveolar macrophages. The large and atypical cells are markedly reactive alveolar type II pneumocytes. The alveolar wall itself is scarred with collagen deposition by the spindle-shaped fibroblasts. *(Reproduced used with permission from Dr. Darryl Carter, Professor of Pathology, Yale School of Medicine.)*

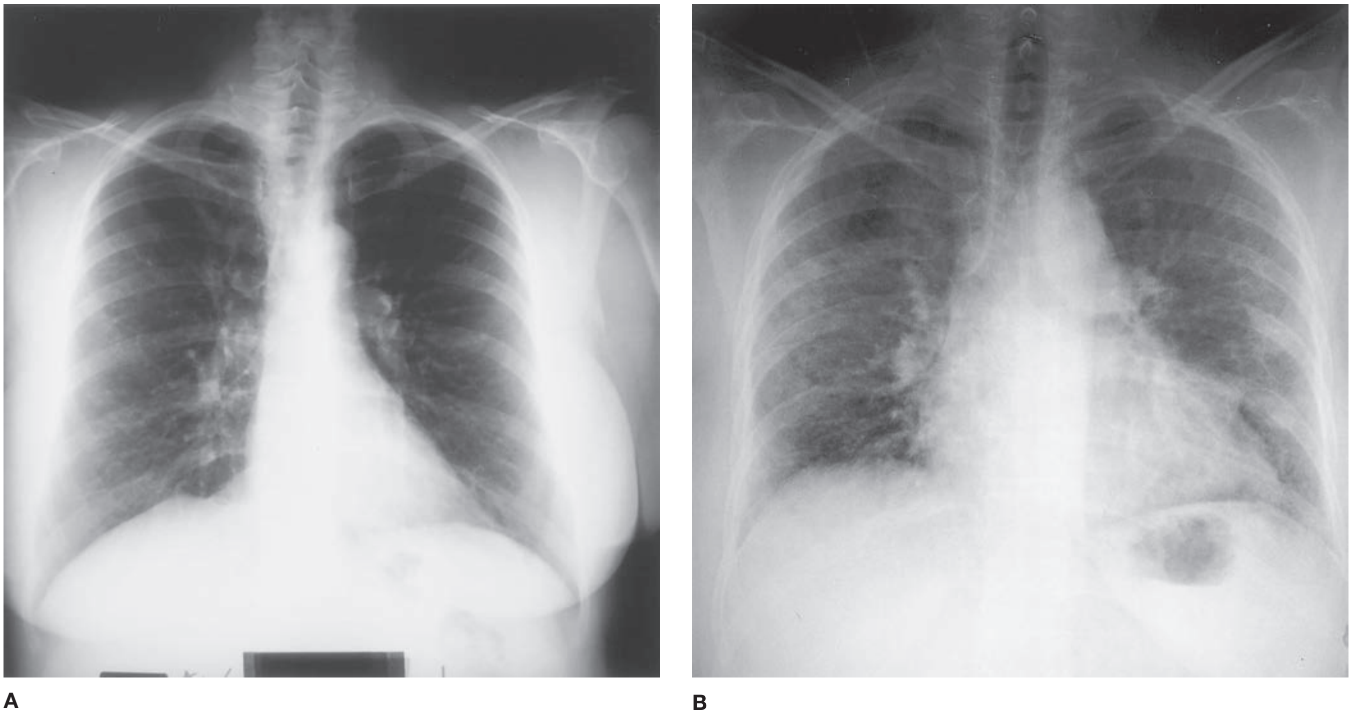

Figure 64-2 Postero-anterior chest radiographs of a 56-year-old woman with cervical carcinoma (**A**) before and (**B**) after chemotherapy with a bleomycin-containing regimen. Note the decrease in lung volume and diffusely increased interstitial lung markings in the post-chemotherapy radiograph.

possible in clinical practice. Cases have been reported of recrudescent pulmonary injury in patients exposed to even modest levels of supplemental oxygen several months after bleomycin exposure, so caution in limiting oxygen exposure for at least 6 months after treatment appears warranted.[19] (3) Thoracic irradiation prior to, concomitant with, or subsequent to bleomycin administration may be associated with an increase in toxicity. This "radiation recall" effect may extend outside the original port of irradiation and may last for years after bleomycin therapy. Delaying radiation for at least 28 days after chemotherapy may mitigate this risk.[20] (4) Bleomycin is excreted by the kidneys, and decreased creatinine clearance below 35 mL/min is associated with increased risk of toxicity.[21] (5) The risk for pulmonary toxicity increases with age; patients over 70 years of age are at particular risk.[22] (6) Concurrent use of bleomycin with other chemotherapeutic agents, including gemcitabine or cisplatin, or in combination with adriamycin/vinblastine/dacarbazine as the ABVD regimen for Hodgkin lymphoma, may result in synergistic toxicity.[20,23] (7) Some studies have suggested that external factors such as smoking or treatment with granulocyte colony–stimulating factor (G-CSF) may increase the risk of bleomycin toxicity, although these reports have not been consistently reproduced.[24,25]

The clinical presentation of bleomycin-induced pneumonitis is usually subacute and insidious, occurring within a few weeks to 6 months after treatment.[9] A more fulminant presentation with acute respiratory failure has been reported but is far less common. Patients may be asymptomatic but generally present with dyspnea, nonproductive cough, low-grade fever, or substernal or pleuritic chest pain. Common physical findings include hypoxemia and fine bibasilar crackles; rhonchi and a pleural rub also may develop.[26] Chest radiograph usually shows low lung volumes with bilateral reticular or fine nodular infiltrates with a basilar predominance, often beginning at the costophrenic angles (Fig. 64-2). However, various radiographic patterns have been described, including alveolar infiltrates, lobar consolidation, organizing pneumonia, asymmetric lung involvement, pneumothorax, pneumomediastinum, and even lung nodules. CT scanning, particularly high-resolution CT (HRCT), is more sensitive in the evaluation of radiographic abnormalities and may be useful in patients who have spirometric or clinical evidence of toxicity but negative chest radiographs (Fig. 64-3).[27] PFT monitoring demonstrates that many patients receiving bleomycin demonstrate a decrease

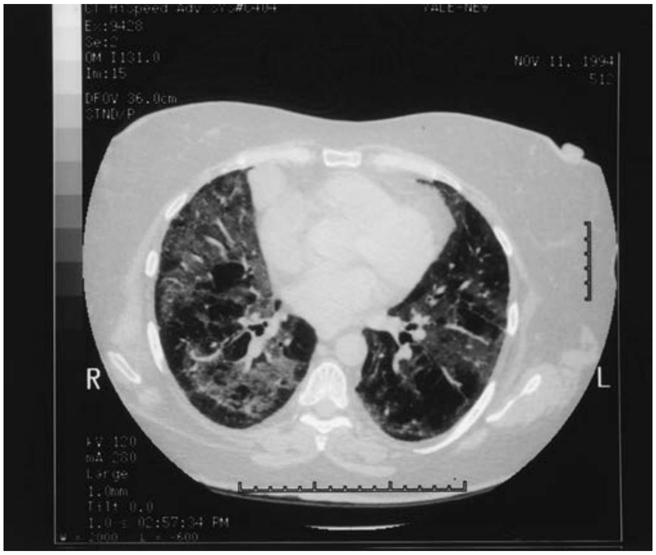

Figure 64-3 Chest computed tomography (CT) scan of same patient as in Fig. 64-2, taken at the time of radiographs in Fig. 64-2. Note the patchy distribution of bilateral infiltrates, the extent of which is clearly delineated by CT.

in $D_{L_{CO}}$ without symptoms over the course of therapy, with only a small percentage manifesting clinical signs of pulmonary toxicity and a decrease in lung volumes.[28]

Bleomycin may also cause an acute hypersensitivity syndrome of dyspnea, cough, and rash immediately following administration of drug. Lung biopsy in these cases shows eosinophilic infiltration and changes consistent with hypersensitivity pneumonitis; peripheral eosinophilia also may be observed. These cases show a particularly favorable response to steroid therapy.[29] An acute chest pain syndrome has also been reported in 1% of patients receiving bleomycin; it occurs during infusion, resolves with termination of drug, and does not appear to predict other pulmonary toxicity from bleomycin.[30]

Discontinuation of drug is recommended for patients with clinically significant bleomycin-induced toxicity and may be sufficient intervention for individuals with mild presentations. For more significant disease, corticosteroids are usually given as prednisone at 1 mg/kg/d for 4 to 8 weeks, with tapering over the next several months guided by clinical stability of the patient and recognizing that the rapidity of the taper will be up to the individual clinician. Response of bleomycin-induced pulmonary toxicity to corticosteroids is highly variable, with more responsive cases likely representing hypersensitivity pneumonitis or organizing pneumonia.[9] When improvement does occur, it is usually seen within weeks of drug cessation, but complete resolution to a stable new baseline may take up to 2 years. Patients may be left with residual radiographic and/or physiologic abnormalities, particularly if fibrosis has developed.

Mitomycin C

Mitomycin C is an alkylating agent derived from *Streptomyces caespitosus*. It is used in multidrug regimens for multiple solid organ malignancies, most commonly for bladder, gastric, pancreatic, cervical, head and neck, and breast cancers. The incidence of pulmonary toxicity due to mitomycin is variably reported between 2% and 38% (with clinically relevant toxicity likely $<10\%$) and appears to be potentiated by concurrent administration of other agents, particularly vinca alkaloids.[31] Although typically associated with intravenous therapy, cases of significant pulmonary toxicity have been reported in patients receiving both intravesicular and intraperitoneal mitomycin C.[32,33] Mitomycin C lung injury presents with multiple distinct pulmonary syndromes, including interstitial pneumonitis and fibrosis, bronchospasm, acute lung injury, thrombotic microangiopathy, veno-occlusive disease with pulmonary hypertension, and pleural disease.

The most common form of mitomycin-induced lung toxicity is a chronic pneumonitis with pulmonary fibrosis similar to that seen with bleomycin; it similarly appears potentiated by exposure to supplemental oxygen or radiation.[34] Some studies have suggested a dose–response effect, with increased risk of toxicity after higher cumulative dose, although this finding has not been consistently reproducible.[34] The exact mechanism of injury is unknown, but several have been proposed, including lipid peroxidant injury, hypersensitivity reactions, or immune complex–mediated disease. Pulmonary toxicity usually occurs after 2 to 12 months of therapy, although a more fulminant form of acute lung injury has been reported after a single dose.[35]

Clinically, patients most often present with a subacute syndrome of cough and progressive dyspnea, often with fatigue and sometimes with pleuritic chest pain.[36] Fever is less common. Chest radiographs usually show bilateral interstitial infiltrates, occasionally with alveolar or fine nodular patterns. PFTs most often demonstrate a restrictive pattern with impairment in $D_{L_{CO}}$.[3] Histologically, biopsy specimens show mononuclear cell infiltration, alveolar-lining cell hypertrophy, collagen deposition, and alveolar septal thickening; type II pneumocyte enlargement and lymphocytic or eosinophilic infiltration also have been described. This syndrome may respond to discontinuation of drug and institution of corticosteroids at an initial dose of 60 mg/d tapered over a 4- to 6-week period.[36]

The second syndrome of mitomycin-induced pulmonary toxicity is seen primarily in patients who have also received vinca alkaloids. While drugs of this latter category (vinblastine, vinorelbine, and vindesine) confer little in the way of risk of pulmonary toxicity when used alone, they may precipitate a syndrome of acute pulmonary toxicity when given concurrently with or subsequent to administration of mitomycin C.[37] Patients present with rapid onset of dyspnea or bronchospasm hours to weeks after exposure; symptoms generally abate in 12 to 24 h with cessation of drug, supportive care, and bronchodilators. In some cases, however, bilateral interstitial infiltrates or noncardiogenic pulmonary edema can develop, and patients may go on to develop chronic interstitial lung disease with permanent physiologic impairment. Rechallenge with vinca alkaloids alone, independent of mitomycin C, can also result in recrudescence of symptoms.[37]

The third syndrome of mitomycin C toxicity is a microangiopathy, with a presentation similar to thrombotic thrombocytopenic purpura and hemolytic uremic syndrome (TTP–HUS). Mitomycin C–associated TTP–HUS is associated with acute lung injury and respiratory failure in 50% of cases.[38] Pulmonary alveolar hemorrhage in this setting also has been described.[39] The mechanism of toxicity appears related to endothelial injury in the pulmonary vasculature. Prognosis is poor as patients with chemotherapy-induced TTP–HUS tend to be refractory to plasmapheresis and corticosteroids that are the typical mainstay of therapy. Cases have been reported of successful treatment with rituximab, but it should be noted that these patients did not have respiratory failure.[40,41]

In addition, mitomycin C has been implicated in two cases of fatal pulmonary hypertension caused by pulmonary veno-occlusive disease in patients with non–small-cell lung cancer (NSCLC).[42] There have also been reports of pleural toxicity, with exudative effusions and pleural fibrosis.[3]

Actinomycin D

Actinomycin D is an older antitumor antibiotic derived from *Streptomyces*, which is still used in treatment of some cancers, including for example Ewing sarcoma, rhabdomyosarcoma, and Wilms tumor. While this drug is not often associated with primary lung toxicity, it may potentiate "radiation recall" pneumonitis in patients who have received prior thoracic irradiation.[43]

■ Alkylating Agents

The chemotherapeutic property of alkylating agents results from their addition of an alkyl group to the guanine base of DNA, which ultimately results in DNA damage. Rapidly dividing cells, including neoplastic cells as well as normal cells of organs such as the skin and gastrointestinal tract, are susceptible to disruption of proliferation with such agents, which may result in both therapeutic effect as well as toxicity.[44] Nitrogen mustards are the prototypic alkylating agents, but many other drugs also exert antineoplastic effects by alkylation. Alkylating agents that have been associated with pulmonary toxicity include nitrogen mustard compounds (cyclophosphamide, melphalan, chlorambucil, ifosfamide, bendamustine), alkyl sulfonates (busulfan), platinum-based therapies (oxaliplatin, cisplatin, carboplatin), and the nitrosoureas (carmustine/BCNU,

TABLE 64-2 Alkylating Agents

Drug	Pulmonary Syndrome	Treatment	Comments
Cyclophosphamide	• Chronic pneumonitis • Pulmonary fibrosis	• Discontinue drug • Corticosteroids	• Risk factors: High cumulative dose, additional cytotoxic drugs, supplemental oxygen; therapeutic radiation • Toxicity may occur years after treatment • Pleural fibrosis may occur in late-stage disease
Busulfan	• Chronic pneumonitis • Pulmonary fibrosis	• Discontinue drug • Consider corticosteroids	• Risk factors: Cumulative dose >500 mg • Often occurs after cessation of drug • Prognosis poor
Oxaliplatin	• Eosinophilic pneumonitis • Organizing pneumonia • Diffuse alveolar damage	• Discontinue drug • Corticosteroids	• Risk factors: Preexisting interstitial lung disease
Chlorambucil Melphalan Ifosfamide	• Chronic pneumonitis • Pulmonary fibrosis	• Discontinue drug • Consider corticosteroids for patients with hypersensitivity features	• Clinical pulmonary toxicity is rare with exception of high dose melphalan (>200 mg/m^2)
Procarbazine	• Hypersensitivity-type pneumonitis	• Discontinue drug • Consider corticosteroids	• Rechallenge associated with recurrence in most patients

lomustine/CCNU). The nitrosoureas are considered in a separate section below.

Nitrogen Mustards: Cyclophosphamide and Other Nitrogen Mustard Compounds

Nitrogen mustards notoriously were initially developed as agents of chemical warfare. Their notable toxic effects on lymphocytes and white blood cells triggered interest in their potential beneficial use in lymphoid neoplasia. The treatment of a patient with lymphosarcoma in 1942 with a nitrogen mustard compound heralded a new era of chemotherapeutic approaches to patients with cancer.[45] Many such compounds continue to be widely used in oncologic practice, including cyclophosphamide, bendamustine, melphalan, chlorambucil, and ifosfamide. Important examples are listed in Table 64-2.

Cyclophosphamide is the most widely used of the nitrogen mustards. It is included as a chemotherapeutic agent in the treatment of many malignancies, including lymphomas, breast and ovarian cancers, and a variety of other solid tumors. It may be given as part of myeloablative conditioning regimens prior to bone marrow or peripheral blood stem cell transplantation. It is also used alone or in combination with corticosteroids in the treatment of nonneoplastic conditions including autoimmune diseases and systemic vasculitides.[7] The overall incidence of cyclophosphamide-induced lung injury is low, generally felt to be $<1\%$, although as with other agents, increased pulmonary toxicity may occur in the setting of radiation therapy, oxygen supplementation, or combination treatment with other cytotoxic agents.[46,47] There is less experience with pulmonary toxicities related to newer nitrogen mustards, but as they are mechanistically related, toxicities are assumed to be similar.[48]

Cyclophosphamide is administered as an inactive prodrug that is metabolized by the liver and to a lesser extent in the lung, to 4-hydroxycyclophosphamide, phosphoramide mustard (responsible for alkylation and DNA cross-linking), and acrolein (responsible for the hemorrhagic cystitis that can complicate therapy).[49] Though the exact mechanism of cyclophosphamide-induced injury to the lung is unknown, in vitro models suggest contributions from oxidative stress and upregulation of TGF-β, increase in collagen synthesis and, ultimately, fibrosis.[50] Cyclophosphamide toxicity lacks a clear dose–response relationship in humans, possibly due to genetic variations in drug metabolism.[51] In addition, the pharmacokinetics of both the inactive parent compound and the active alkylating derivative can be affected by variations in the cytochrome P450 superfamily of enzymes, as well as by interactions with other drugs. Functionally higher exposure to active drug may occur in the setting of substances that induce hepatic enzyme activity, such as rifampin, phenytoin, and alcohol, or with decreased renal clearance.

As with a number of other chemotherapeutic agents, cyclophosphamide-induced pulmonary toxicity may present either early in the course of treatment or in a delayed, progressive fashion that may begin years after treatment is completed. In cases where pulmonary symptoms occur long after exposure, an association with the drug may be difficult to identify. Clinical features are nonspecific, including nonproductive cough, dyspnea, fatigue, and fever. Occasionally, patients are asymptomatic but are discovered to have radiographic abnormalities compatible with drug toxicity. Chest radiographs and CT scans usually show evidence of bilateral interstitial lung disease (either bilateral reticular or nodular markings with ground-glass opacities or, later, fibrosis) and may also show pleural fibrosis in late-stage disease.[52] This latter radiographic finding may be helpful in distinguishing cyclophosphamide-associated interstitial lung disease from the idiopathic interstitial pneumonias.

Histologic findings in the lung are not specific. Lung biopsy in these patients is useful primarily for exclusion of other identifiable causes of interstitial infiltrates in immunocompromised patients, including infection and malignancy. When used to treat nonneoplastic lung disease, the distinction between underlying lung disease from a systemic syndrome and lung disease exacerbated by drug toxicity is often very difficult to delineate. When cyclophosphamide is used as a chemotherapeutic agent, it is rarely used alone, and thus pinpointing specific toxicity to a single agent may be impossible.

Cyclophosphamide-induced lung injury may cause significant morbidity, and a high clinical suspicion for pulmonary toxicity should result in prompt discontinuation of the drug. Early-onset pneumonitis can occasionally be fatal, but when recognized quickly, prognosis is generally favorable and recovery, while slow, is expected for most individuals. Discontinuation of the drug alone may be sufficient, although the clinical threshold to add glucocorticoid therapy is often low. The optimal regimen and magnitude of benefit in these cases remain unclear.[53] Late-onset toxicity is uncommon but can follow an irreversible and progressive, steroid-unresponsive course; mortality due to progressive respiratory failure exceeds 60%.[52]

Chlorambucil and melphalan are both slow-acting nitrogen mustards. Chlorambucil has an important role in the treatment of lymphoreticular malignancies including chronic lymphocytic leukemia (CLL) and has, in the past, also been used in the treatment of nonneoplastic diseases, such as rheumatoid arthritis and sarcoidosis. Pulmonary toxicity is less common than with other alkylating agents, occurring in <1% of patients; pulmonary fibrosis is uncommon, but when it occurs is associated with mortality in excess of 50%.[54] Chlorambucil may be administered over a prolonged time in the treatment of CLL, but there does not appear to be a clear relationship between toxicity and either cumulative dose or duration of therapy. The number of cases of reported chlorambucil pulmonary toxicity is relatively small; thus no distinct clinical pattern has emerged. In cases of chlorambucil-related interstitial pneumonitis, BAL has demonstrated a CD8+ T cell alveolitis suggestive of hypersensitivity reaction.[55] Given the possibility of hypersensitivity pneumonitis, clinical suspicion should prompt immediate discontinuation of the drug, and administration of corticosteroids can be considered in patients with progressive pulmonary disease.

Melphalan has traditionally been used in the treatment of multiple myeloma, but, like other alkylating agents, it is now used to treat a variety of malignancies. High-dose melphalan (200 mg/m^2 or more) is used in conditioning regimens prior to stem cell transplantation and has been associated with fatal pneumonitis and fibrosis.[56] Since large series of such patients are not available, the incidence of pulmonary toxicity associated with high-dose melphalan given in these situations is not known.

Ifosfamide is a nitrogen mustard that is structurally related to cyclophosphamide. It is used in the treatment of lymphoma and acute and chronic leukemias, as well as in solid tumors including sarcomas, ovarian cancer, and breast cancer. Dose limitation is usually related to bladder toxicity. Clinically evident ifosfamide-induced pulmonary toxicity appears to be rare and typically presents as interstitial pneumonitis.[57] It has also been described as a cause of acquired methemoglobinemia presenting as shortness of breath and confusion; this should be considered in the differential for patients on ifosfamide presenting with dyspnea, cyanosis, or altered mental status.[58]

Procarbazine is an alkylating agent used primarily in the treatment of lymphoma; it is associated with hypersensitivity pneumonitis and eosinophilia in a small number of patients.[59] This syndrome typically is seen after the second or third cycle of chemotherapy, although earlier as well as later occurrences have been described. Cough, dyspnea, and fever are typical symptoms, with the development of radiographic interstitial and/or alveolar infiltrates. A variable response to corticosteroids is reported, and rechallenge with procarbazine is associated with recurrence of the syndrome in the majority of patients.

Bendamustine is a newer nitrogen mustard compound used predominantly in combination regimens for lymphoid malignancies. A large study examining bendamustine-based conditioning regimens prior to autologous stem cell transplantation for treatment of lymphoma in 474 patients was triggered by a shortage of carmustine, for which bendamustine was substituted in combination with etoposide, cytarabine, and melphalan (BeEAM).[60] Notably, no severe pulmonary toxicities were noted with this regimen, although other toxicities including a higher incidence of acute kidney injury were observed.

Alkyl Sulfonates: Busulfan

Busulfan is now primarily used as a component of conditioning regimens for bone marrow and stem cell transplantation. Since these ablative regimens may not always be recognized as part of the active treatment protocol, clinicians need to recognize the specific drugs that were used solely for pretransplant conditioning. Toxicity may develop within weeks of exposure but is more typically insidious; one of the characteristic features of busulfan toxicity is this delay, with the average onset of symptoms being more than 3 years after treatment.[7] Estimates of frequency vary widely, with an average of approximately 6%.[61] As with chlorambucil for CLL, patients receiving busulfan for CML were often treated for months to years with the drug. Although it was generally well tolerated in this setting, patients receiving a cumulative dose above 500 mg appeared to be at higher risk for pulmonary complications.[62]

As noted, busulfan is currently used in conditioning regimens prior to bone marrow and stem cell transplantation. Pulmonary complications in this situation are not uncommon, and it may be difficult to clearly attribute toxicity to busulfan rather than other, more likely causes including infection, radiation-induced pneumonitis, and effects of other drugs.[63,64] In long-term comparisons of patients receiving busulfan and cyclophosphamide versus total body irradiation prior to allogeneic transplantation, bronchiolitis obliterans was far more frequent in the former group (26% vs. 5%), while rates of pneumonitis were similar; this raises the concern that the main source of pulmonary toxicity in busulfan-based conditioning regimens may be an increase in chronic pulmonary graft-versus-host disease.[65]

Symptoms of busulfan lung injury usually present insidiously, weeks to years after exposure, with cough, progressive dyspnea, fever, fatigue, and weight loss. Chest radiographs typically show bilateral interstitial infiltrates with a basilar predominance. Pathologic findings are consistent with other cytotoxic drug–induced pulmonary injuries, with type II pneumocyte hyperplasia, dysplasia, and desquamation into alveolar spaces. Fibroblast proliferation, collagen deposition, and fibrosis are usually evident. Desquamation and accumulation of alveolar debris can be severe in some cases, yielding a pattern similar to pulmonary alveolar proteinosis; unfortunately, total lung lavage is usually ineffective in such cases.[7,66]

There is no specific treatment for busulfan-induced pulmonary injury, except withdrawal of drug. However, due to the delayed nature of presentation, patients are often no longer on therapy by the time toxicity is detected; treatment is thus largely supportive. Although some spontaneous improvement may occur, when there is clinically evident busulfan-induced pulmonary toxicity the prognosis for recovery is generally poor. Corticosteroids have anecdotally been reported to be of benefit, but, as with most chemotherapeutic agents, no prospective studies are available. Given the possibility of late-onset pulmonary toxicity, it seems prudent that long-term follow-up of recipients of bone marrow or peripheral blood stem cell transplants with busulfan-based conditioning regimens should include pulmonary evaluation. However, evidence-based direction for identification or treatment of pulmonary toxicity in this situation is lacking.

■ Platinum-Based Chemotherapeutic Agents

In general, pulmonary toxicity related to the older platinum-based chemotherapeutic agents, cisplatin and carboplatin, is uncommon. These drugs have been the backbone of doublet therapy for advanced-stage non–small-cell lung cancer (NSCLC) for several decades. There has been substantial experience using platinum-based regimens in large numbers of NSCLC patients, many of whom have underlying nonneoplastic lung disease, with relatively little pulmonary toxicity attributed to the platinum half of the doublet.

Oxaliplatin is a newer platinum derivative, primarily used as part of multidrug regimens with 5-fluorouracil and leucovorin (FOLFOX) for treatment of colorectal cancer, as well as for treatment of pancreatic, breast, and ovarian cancers. As with the other platinum agents, pulmonary complications are uncommon, although several patterns of lung toxicity have been reported with FOLFOX regimens including eosinophilic pneumonia, organizing pneumonia, and diffuse alveolar damage.[67–70] The timing, severity, progression, and prognosis of individual cases have been heterogeneous, probably owing to the diversity in pathologic mechanisms. Some cases have demonstrated complete resolution with withdrawal of drug, with or without administration of corticosteroids, but others have progressed rapidly to respiratory failure and death.[68,70] In some cases, patients were successfully rechallenged with 5-fluorouracil and leucovorin, implicating oxaliplatin as the likely culprit in the original adverse reaction.[67,69] Mechanisms of toxicity are poorly understood and likely multifactorial; glutathione depletion has been suggested based on the mechanistic role in oxaliplatin-induced hepatic injury, and based on an anecdotal case report of an individual who improved when treated with a combination of corticosteroids and N-acetylcysteine.[71,72] Patients with pre-existing interstitial lung disease, even when subclinical, may be at increased risk for oxaliplatin toxicity, progression of underlying interstitial disease, or both.[72] Individuals with baseline physiologic and radiographic abnormalities, even in absence of symptoms, should be monitored carefully, and the threshold for withdrawal of drug and trial of corticosteroids should be low.

Nitrosoureas: BCNU, CCNU, Semustine, Chlorozotocin

The nitrosoureas (Table 64-3) include carmustine (BCNU, 1,3-bis-(2-chloroethyl)-1-nitrosourea), lomustine (CCNU, 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea), semustine (methyl-CCNU), and chlorozotocin. These cytotoxic drugs are active against a variety of neoplasms. BCNU and CCNU are highly lipophilic and can cross the blood–brain barrier, which makes them particularly useful in the treatment of central nervous system malignancies. BCNU is also used in high-dose conditioning regimens prior to bone marrow or stem cell transplantation for a variety of malignancies, including breast cancer, Hodgkin and non-Hodgkin lymphomas, multiple myeloma, and gliomas.

Of the nitrosoureas, BCNU has been most extensively studied. Like bleomycin, this drug has been used in animal models of lung injury. BCNU exposure in rodents has been observed to result in type II pneumocyte cellular toxicity and granulomatous inflammation, eventually leading to interstitial fibrosis that progresses even after withdrawal of drug.[73] Oxidant lung injury may play a role in the pathogenesis of toxicity, as BCNU is known to inhibit glutathione reductase in pulmonary macrophages and reduces lung glutathione stores; however, the exact mechanisms by which pulmonary fibrosis occur are not well defined.[74]

Like bleomycin, BCNU toxicity appears to be dose related. In a study of 94 patients with Hodgkin lymphoma who received chemotherapeutic regimens including BCNU, doses less than 475 mg/m^2 were associated with a 15% incidence of pulmonary toxicity; doses ranging between 475 and 525 mg/m^2 with a 32% incidence; and doses in excess of 525 mg/m^2 with a 47% incidence of pulmonary toxicity.[75] Treatment of intracranial gliomas may result in substantially higher cumulative BCNU doses. Very high doses (>1200–1500 mg/m^2) result in pulmonary toxicity in as many as 20% to 50% of patients.[75–77] Of note, BCNU may be used in single high doses pre–bone marrow or stem cell transplantation or may be given sequentially over longer periods of time. Whether the pattern of administration of a given total dosage has an impact on the potential for lung injury is unknown. Reported risk factors contributing to the development of pulmonary toxicity with BCNU include underlying lung disease, a history of smoking, previous or simultaneous treatment with other chemotherapy agents (including cyclophosphamide or bleomycin), chest radiotherapy, and female sex; of these, higher dose and female sex are most consistently associated with development of pulmonary fibrosis.[76,78–81]

Pulmonary fibrosis related to BCNU falls into two patterns: an early-onset group that typically occurs within days to weeks of treatment or up to 3 years, and a late-onset group that may present years later. Early-onset pulmonary injury appears to be an underappreciated event. In a study of 152 patients treated for breast cancer with a regimen of BCNU (600 mg/m^2), cyclophosphamide, and cisplatin followed by stem cell transplantation, 59% developed a significant decrease in DL$_{CO}$ at a median time after treatment of 45 days.[76] The vast majority of patients had subclinical disease and appeared to have improvement in their pulmonary status with initiation of corticosteroid therapy. Early-onset toxicity can also present as fulminant lung injury with progression in some cases to fatal pulmonary fibrosis.[81,82]

Late-onset pulmonary toxicity, typically presenting as pulmonary fibrosis, may occur years after BCNU treatment. In 1990, O'Driscoll et al. first reported their observations on this phenomenon in survivors of childhood brain tumors.[79] Of 31 original patients, 14 died of their tumors. In a 25-year follow-up report of the 17 survivors, 9 (53%) had died of complications related to pulmonary fibrosis.[83,84] Two patients died within the first 3 years after chemotherapy, 4 died between 6 and 13 years after chemotherapy, and 3 died between 13 and 25 years after chemotherapy. Furthermore, of the remaining 8 patients still surviving, 7 had radiographic and physiologic evidence of pulmonary fibrosis. Thus, in this population of children treated with high-dose BCNU, late toxicity in the lung was extremely common and of severe clinical consequence years after treatment.

The clinical presentation of BCNU-induced lung toxicity is variable. As noted, it may present as fulminant acute respiratory failure but more commonly presents insidiously with asymptomatic physiologic abnormalities or radiographic evidence of pulmonary fibrosis. Symptoms of the latter subacute course include cough, fatigue, and progressive dyspnea. Chest radiograph is rarely normal in symptomatic patients, usually showing bilateral interstitial infiltrates with a basilar predominance. However, in O'Driscoll's series of patients with childhood brain tumors treated with high-dose BCNU who developed late-onset pulmonary fibrosis, patients demonstrated an upper lobe predominance to the distribution of fibrotic changes.[79,83,84] Patients with an acute presentation may present with confluent

TABLE 64-3 Nitrosoureas

Drug	Pulmonary Syndrome	Treatment	Comments
Carmustine (BCNU)	• Early-onset interstitial lung disease	• Discontinue drug • Corticosteroids	• Risk factors: total dose, female sex, underlying lung disease, cigarette smoking, combination treatment with other cytotoxic drugs
	• Late-onset pulmonary fibrosis	• May appear years after treatment	
Lomustine Semustine Chlorozotocin	• Interstitial lung disease	• Discontinue drug	• By extrapolation, toxicities and risk factors probably similar to BCNU

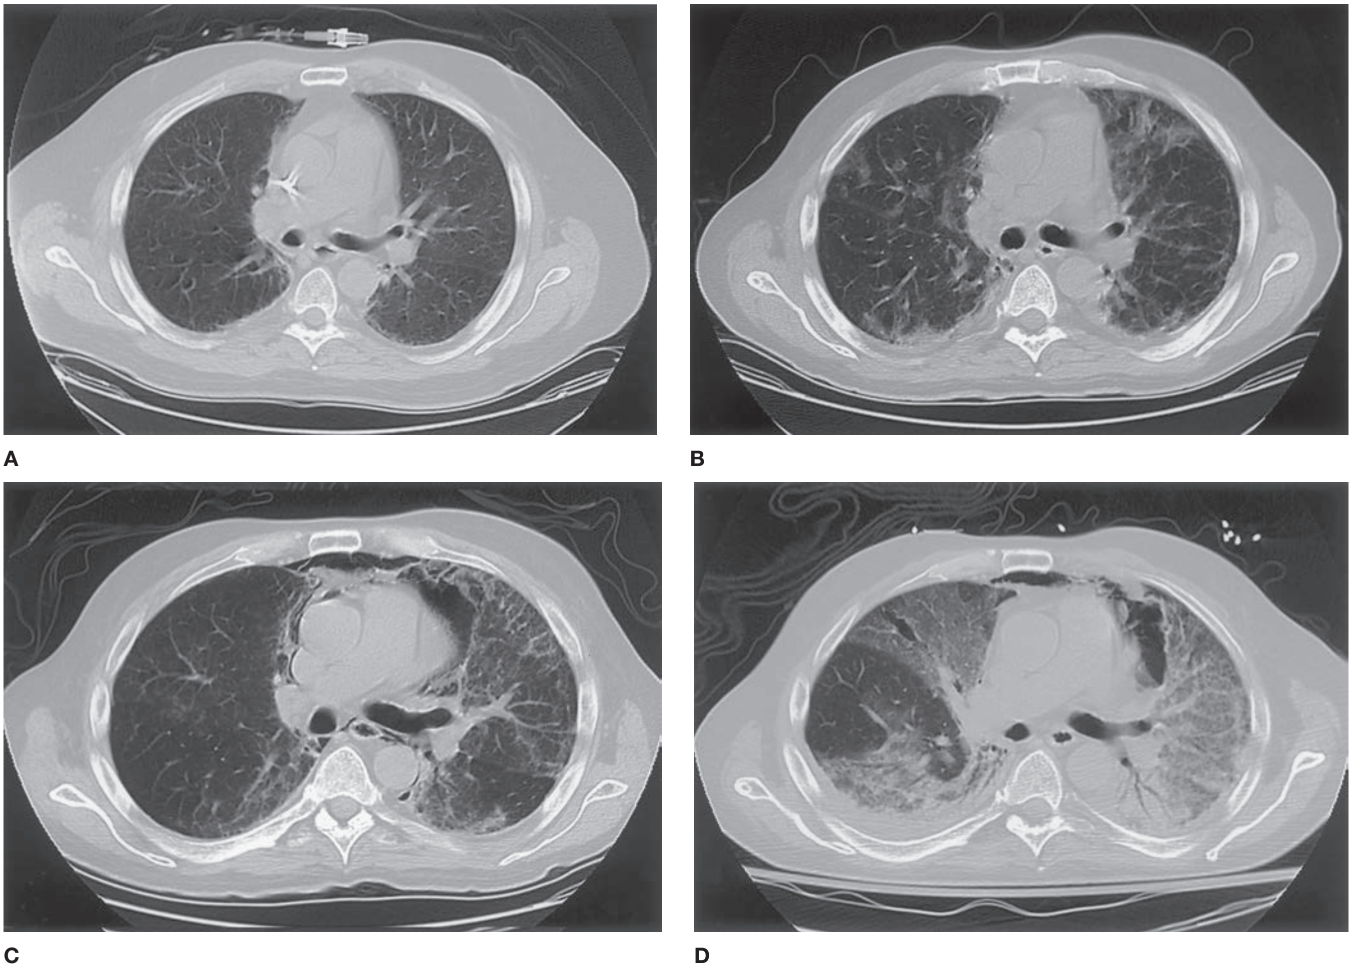

Figure 64-4 Serial chest computed tomography (CT) images of a 54-year-old man with a history of Hodgkin lymphoma, treated with a BCNU-containing regimen. The dates of the examinations span 6 months from **A** to **D**. Note the progression of diffuse interstitial patchy infiltrates, starting with the baseline normal study in **A**. Pneumomediastinum and left pneumothorax are seen in **C** and **D**. Bronchoscopy performed between examinations **B** and **C** demonstrated no evidence of infection. The patient had progressive dyspnea and respiratory insufficiency and eventually died of respiratory failure.

alveolar infiltrates. Pneumothorax has been described in a number of cases and may be bilateral (Fig. 64-4). Pulmonary physiology generally shows a restrictive ventilatory defect, with diffusion abnormalities and eventually hypoxia. As with bleomycin-related lung injury, $\mathrm{DL_{CO}}$ may decrease without radiographic or clinical evidence of disease. While it has been suggested that a decrease in $\mathrm{DL_{CO}}$ may be the earliest sign of pulmonary toxicity, prospective evaluation of screening pulmonary function studies in the diagnosis of BCNU-induced lung toxicity has not been adequately studied. However, in light of the frequency and severity with which BCNU-associated pulmonary injury appears to occur, PFT may be helpful in identifying patients at risk and in whom administration of corticosteroids might be considered. Since BCNU toxicity is common, and the likelihood of progression of BCNU-related lung injury to significant pulmonary fibrosis appears high, it could be argued that surveillance with PFT should be considered, particularly if high doses of drug are to be given.

Pathologic changes in the lung from BCNU parallel those seen with other cytotoxic agents. Type II pneumocyte hyperplasia and dysplasia, fibroblast proliferation, and deposition of proteinaceous material in alveoli have been described. However, inflammation tends not to be a prominent histologic feature, and the cardinal feature of BCNU-induced lung toxicity appears to be interstitial fibrosis. In some cases, angiocentric necrotizing granulomatous inflammation or, more rarely, pulmonary veno-occlusive disease may be seen.

The prognosis for patients with BCNU-induced lung injury is poor. For patients with early-onset lung toxicity, treatment with corticosteroids may be effective. One study of patients with breast cancer for whom BCNU was administered as part of treatment with high-dose chemotherapy followed by stem cell transplantation suggested that inhaled corticosteroids might be helpful in preventing pulmonary toxicity.[85] Late-onset pulmonary fibrosis related to BCNU does not appear to respond to corticosteroid therapy. The primary approach to BCNU toxicity should be prevention, that is, administer the lowest possible effective dose and monitor closely for signs of toxicity. Long-term treatment remains supportive. With the known long potential delay in the onset of signs of toxicity, long-term pulmonary follow-up also is warranted.

The other nitrosoureas used as chemotherapeutic agents, lomustine (CCNU), semustine (methyl CCNU), and chlorozotocin, also have been described to cause pulmonary toxicity. In general, these drugs have been used less widely than BCNU and in smaller cumulative doses. Their described lower incidence of pulmonary toxicity is likely due to these factors. As with BCNU, toxicity tends to present insidiously with interstitial pneumonitis and pulmonary fibrosis. However, given their close chemical relation, the potential for severe lung toxicity as seen with BCNU must be taken into consideration when using other drugs of this class.

TABLE 64-4 Antimetabolites

Drug	Pulmonary Syndrome	Treatment	Comments
Methotrexate	• Chronic pneumonitis • Pulmonary fibrosis	• Corticosteroids • Discontinue drug	• Most common syndrome of methotrexate-induced lung toxicity • Risk factors: older age, pre-existing lung disease, diabetes, previous use of disease-modifying drugs, hypoalbuminemia
	• Hypersensitivity-type lung disease	• Corticosteroids • Discontinue drug	• May resolve even if drug is continued, but can progress to fibrosis
	• Acute chest pain syndrome	• Discontinue drug	• Often accompanied by pleural effusions
	• Noncardiogenic pulmonary edema	• Supportive care • Discontinue drug	• Associated with intrathecal administration
Cytosine arabinoside	• Noncardiogenic pulmonary edema	• Supportive care • Discontinue drug	• Onset of symptoms usually occurs within days of initiation of treatment • Risk factor: higher cumulative dose
	• Cryptogenic organizing pneumonia	• Discontinue drug • Corticosteroids	• Risk factors: combined therapy with anthracyclines or interferon α
Fludarabine	• Hypersensitivity-type lung disease • Interstitial pneumonitis	• Discontinue drug	• Toxicity is uncommon • Treatment associated with increased incidence of delayed opportunistic infections
Gemcitabine	• Dyspnea	• Occurs within hours of dose	• Usually self-limited
	• Interstitial lung disease • Noncardiogenic pulmonary edema	• Discontinue drug • Corticosteroids • Diuretics	• Risk factors: combination treatment with taxanes or bleomycin

■ Antimetabolites

Antimetabolites as chemotherapeutic agents include an array of different compounds, all of which can be associated with lung injury (Table 64-4). Representative examples are discussed below.

Methotrexate

Methotrexate is an analogue of folic acid. It has several antimetabolic pathways, but the predominant mechanism of its ability to decrease cellular proliferation relates to decreased activation of folic acid through competitive inhibition of dihydrofolate reductase. The downstream effect of this is inhibition of thymidine, purine, and pyrimidine synthesis, with consequent inhibition of DNA, thymidylates, and protein synthesis.[86] Methotrexate is used to treat malignancies as well as connective tissue diseases and other inflammatory conditions, particularly rheumatoid arthritis. Its initial use for treatment of acute lymphoblastic leukemia in children also resulted in identification of pulmonary toxicity. In the original report by the Acute Leukemia Group B, "pneumonitis" was observed in 38 of 93 children treated with methotrexate maintenance therapy, including 3 fatal cases.[87] This report should be tempered by the recognition that "pneumonitis" does not appear to have been definitively exclusive of infection, and that these children were also treated with other drugs, including vincristine and prednisone. Subsequent estimates of the incidence of pulmonary toxicity are substantially lower, typically in the 1%–8% range, but have largely been reported in non-oncologic populations, where methotrexate is typically given in low doses for long periods of time (months to years), as opposed to high doses over short time frames that would be more typical when the drug is used chemotherapeutically.[88–90] Further, when methotrexate is used for cancer treatment, it is rarely used alone, making interpretation of its role in any pulmonary syndrome challenging. Additionally, in patients with rheumatoid arthritis or other connective tissue or inflammatory diseases, the potential for a variety of pulmonary manifestations related to the underlying disease can make the diagnosis of methotrexate-induced pneumonitis challenging.

Diagnostic criteria for methotrexate-associated pulmonary toxicity have been proposed by Kremer and colleagues, based on the initial criteria suggested by Searles and McKendry in 1987 (Table 64-5).[90,91] These criteria have never been validated in a

TABLE 64-5 Recommended Diagnostic Criteria for Adverse Pulmonary Events Associated with Methotrexate Treatment for Rheumatoid Arthritis[91]

Major criteria

1. Hypersensitivity pneumonitis by histopathologic examination (without evidence of pathogenic organisms)
2. Radiologic evidence of pulmonary interstitial or alveolar infiltrates
3. Blood and sputum cultures negative for pathogenic organisms

Minor criteria

- Shortness of breath of <8 weeks' duration
- Nonproductive cough
- O_2 saturation ≤90% on room air
- D_{LCO} ≤70% predicted
- WBC ≤15,000/mm^3

Presence of methotrexate toxicity:

- Definite: presence of major criterion 1, or major criteria 2 and 3, and at least 3 minor criteria.
- Probable: presence of major criteria 2 and 3, and 2 minor criteria

prospective cohort, and were intended for situations where methotrexate was used for treatment of rheumatoid arthritis, not cancer. Nonetheless, they provide a framework for a structured approach to methotrexate-related pulmonary toxicity, and may be useful in approaching a patient for whom methotrexate has been used chemotherapeutically for malignancy.

In a multicenter case-control study of methotrexate-induced lung toxicity in patients with rheumatoid arthritis, Alarcon et al. identified risk factors associated with the development of pneumonitis, including age greater than 60 years (associated with a sixfold increase in risk of pneumonitis compared with those <50 years of age), prior history of rheumatoid pleuropulmonary disease, diabetes, previous use of disease-modifying antirheumatic drugs, and hypoalbuminemia.[92] Toxicity does not have consistent dose dependency, but daily versus weekly administration and higher weekly doses of methotrexate have been suggested as associated with increased risk, as well as pre-existing lung disease, prior PFT abnormalities, and the presence of renal insufficiency.[5,93–95] Synergistic toxicity has been reported with combination therapy using cyclophosphamide. Tapering of corticosteroid therapy or adrenalectomy may also increase the risk of methotrexate-induced toxicity.[5,96]

The mechanism(s) of methotrexate-induced lung injury is unknown. Clinically, toxicity presents with several syndromes. The most common of these is development of a symptom complex characterized by fever, dyspnea, cough, malaise, and myalgias, usually within weeks after initiation of therapy. Chest radiography usually shows diffuse interstitial infiltrates but may demonstrate unilateral or bilateral effusions, a nodular appearance, hilar and/or mediastinal adenopathy, or may be normal. Rash is present in up to 17% of patients and peripheral blood eosinophilia in up to 40% of patients.[97] BAL in this setting may show a lymphocytic alveolitis, suggestive of a hypersensitivity reaction.[88] However, illness may resolve even with continuation of the drug, and rechallenge does not necessarily result in relapse, suggesting that hypersensitivity may not be the true mechanism of injury. This presentation of methotrexate-induced pulmonary toxicity mirrors the hypersensitivity-type syndrome that is sometimes observed with bleomycin. As some patients may go on to develop chronic pneumonitis and pulmonary fibrosis, the drug is generally withdrawn when toxicity occurs.

Pulmonary toxicity from methotrexate may also present as a more insidious subacute syndrome of interstitial lung disease. Symptoms including cough, fever, dyspnea, headache, and malaise typically occur within 4 months after the initiation of treatment. Radiographically and clinically this syndrome more closely resembles the type of chronic pneumonitis seen with other cytotoxic drugs and has been reported with all routes of methotrexate administration (oral, intravenous, intrathecal). In contrast to the lung injury associated with many other chemotherapeutic agents, the pneumonitis caused by methotrexate appears, in general, to be responsive to corticosteroids. Pathologic findings in the lung parallel those seen with lung injury due to other cytotoxic drugs, with interstitial and alveolar inflammation and fibrosis.[7,88] In addition, eosinophilic infiltration of the interstitium as well as granulomatous inflammation may be observed. These latter findings are again suggestive of a potential hypersensitivity-type mechanism of inflammation.

In addition to the above, methotrexate-induced lung injury may also appear as an acute syndrome with pleuritis and pleural effusion. Respiratory distress progressing to noncardiogenic pulmonary edema has been described after intrathecal administration of the drug and may be neurogenic in origin.

The prognosis with methotrexate-associated lung toxicity is generally thought to be favorable. As noted, symptoms and radiographic abnormalities may resolve even with continuation of treatment, although rechallenge should be avoided if possible. The use of corticosteroids is generally recommended, but prospective trials of this intervention are not available.

Cytosine Arabinoside

Cytosine arabinoside (Ara-C) is a pyrimidine nucleoside analogue that rapidly inhibits DNA synthesis. It is important in the treatment of acute leukemias and non-Hodgkin lymphoma. Pulmonary toxicity parallels intensity of treatment; high-dose regimens are associated with a 5% to 44% incidence of acute or subacute respiratory insufficiency.[5,98,99] Symptoms include fever, cough, dyspnea, and tachypnea; their onset may coincide with chemotherapeutic treatment or may be delayed for up to several weeks after treatment is initiated. Hypoxemia may be present. Chest radiograph generally shows a diffuse interstitial or alveolar pattern.

The pathogenesis of pulmonary toxicity due to Ara-C is unknown, but it appears to result in noncardiogenic pulmonary edema. In an autopsy series of 181 patients who died of acute leukemia, Haupt et al. described a group of 42 patients who had received Ara-C within 30 days of death and who had moderate to severe pulmonary edema.[100] Lung pathology showed protein-rich infiltrates in both alveoli and interstitium. Of these 42 patients, 28 had no other identifiable cause of their pulmonary edema. In these cases, Ara-C was thought to be the most likely culprit. Treatment for Ara-C lung toxicity is standard supportive care for noncardiogenic pulmonary edema. Administration of corticosteroids has been recommended by some authors but is of unclear benefit.

Ara-C has also been associated with cryptogenic organizing pneumonia when administered with anthracyclines or IFN-α.[101,102] The pulmonary manifestations typically occur within a few weeks to 2 months after drug exposure and are characterized by fever, shortness of breath, and radiographic infiltrates that may be either lobar or nodular. All patients reported to date have achieved resolution of their pulmonary disease, either spontaneously or with the use of corticosteroids. Overall mortality associated with Ara-C–induced pulmonary toxicity ranges from 6% to 13%.[7,98,100–102]

Gemcitabine

Gemcitabine is a pyrimidine analogue used in the treatment of cancers of the lung, pancreas, ovary, and uroepithelium. It is structurally similar to cytosine arabinoside. Gemcitabine is generally well tolerated when used as a single agent, which may make it appealing for use in older patients. Myelosuppression is its major toxicity. The most common respiratory complaint is dyspnea, which occurs in less than 1% of patients.[103] Dyspnea may occur within hours to days of treatment and is generally self-limited. More serious pulmonary side effects, including interstitial lung disease, pulmonary fibrosis, and acute respiratory distress syndrome, are reported much more frequently when gemcitabine is used in combination with other chemotherapeutic agents. Gemcitabine appears to have a reasonable safety profile when given with carboplatin, a treatment regimen often used for NSCLC.[2] However, severe pulmonary toxicity appears to be much more common when gemcitabine is given in combination with taxanes or bleomycin.[104–107] Acute respiratory distress has been reported with these regimens, with development of noncardiogenic pulmonary edema characterized radiographically by mixed interstitial and alveolar infiltrates. Although responses to diuretics and corticosteroids have been noted, severe pulmonary complications in this setting can be fatal. Histologic evaluation most commonly reveals type II pneumocyte hyperplasia, interstitial inflammation, and hyaline membrane formation, consistent with acute lung injury. Some patients with ultimately fatal outcome have demonstrated early symptomatology, including dyspnea, hypoxemia, and radiographic infiltrates to a milder degree with prior doses of gemcitabine. Such findings should raise consideration for discontinuation of gemcitabine.

Fludarabine

Fludarabine monophosphate is a purine nucleotide analogue used in the treatment of CLL, low-grade non-Hodgkin lymphoma, and a variety of other lymphoproliferative disorders. A major clinical issue related to pulmonary complications with fludarabine therapy is the profound immunosuppression that may persist for months after treatment. The persistent nature of this immunosuppression is unusual when compared to other chemotherapeutic agents. The risk of opportunistic infections, including *P. jirovecii* pneumonia is increased by the use of corticosteroids in this setting. Therefore, symptomatic pulmonary disease in patients treated with fludarabine within this time frame is most likely to be related to infection.

Pulmonary toxicity from fludarabine, including interstitial pneumonitis and acute eosinophilic pneumonitis, is uncommon but has been described.[108–110] Helman et al. reported the largest series to date, which included 9 patients with fludarabine-related pulmonary toxicity out of a total of 105 patients (8.6%) treated with fludarabine over an 11-year period at a single institution.[108] Toxicity did not correlate with age, prior treatment regimens, or history of prior lung disease, but it occurred more frequently in patients with CLL compared to those with other lymphoproliferative disorders. The onset of symptoms ranged from 3 to 6 days after therapy, with radiographs notable for new interstitial or mixed interstitial and alveolar infiltrates. BAL fluid revealed increased cellularity without a consistently predominant cell type. Multifocal nodular pulmonary infiltrates also have been described.[110] Biopsy specimens most commonly reveal diffuse, chronic interstitial inflammation, and fibrosis, although in some cases granulomas have been observed, suggesting the possibility of a hypersensitivity reaction. In the report by Helman et al., patients with fludarabine-associated pulmonary toxicity generally demonstrated subjective and objective improvement with corticosteroid therapy.[108] Most patients responded within days, although more delayed responses also were seen. Recrudescence of noninfectious pulmonary infiltrates has been described with fludarabine retreatment; thus, fludarabine should be avoided in future regimens in patients who have developed drug-related pulmonary toxicity.

■ Miscellaneous Chemotherapeutic Agents

A number of other agents used in treating malignant disease have been reported to be associated with pulmonary toxicity (Table 64-6). Representative examples are discussed below.

Taxanes

The taxane family includes paclitaxel, docetaxel, nab-paclitaxel, and cabazitaxel. Their therapeutic effect derives from inhibition of microtubule disassembly, with disruption of the G2 and M phases of the cell cycle. Paclitaxel, docetaxel, and nab-paclitaxel have activity against a variety of carcinomas, including breast and ovarian cancers and NSCLC, while cabazitaxel is used primarily for advanced prostate cancer. Several pulmonary toxicity syndromes have been described with taxanes.

- Interstitial pneumonitis is the most commonly seen toxicity and is associated more with paclitaxel and docetaxel than the other taxanes. Up to 5% of patients in clinical trials developed pneumonitis sufficient to require intervention or cessation of drug.[107,111–118] Factors that may be associated with an increased risk of pneumonitis include weekly versus every-3-week administration, the presence of pre-existing lung disease (particularly interstitial lung disease), combination treatment with gemcitabine, and concurrent chest irradiation. Symptoms (predominantly progressive dyspnea) may occur within a few weeks of drug initiation or may occur months into treatment. Signs and chest imaging are consistent with interstitial lung disease, with diagnosis based on exclusion of infection, pneumonitis from other causes, and other syndromes including alveolar hemorrhage (Fig. 64-5). BAL is often performed to exclude infection and may demonstrate a lymphocytic or eosinophilic predominance. The approach to a patient with presumed taxane-induced pneumonitis should include cessation of drug. Glucocorticoids should be considered for patients with evidence of more severe toxicity, including hypoxemia and progressive interstitial radiographic changes or physiologic impairment. Clinical vigilance for this group is warranted, as progression to respiratory failure and death can occur.
- Docetaxel can result in a syndrome of fluid retention related to capillary leakage.[118–120] This syndrome is characterized by the development of peripheral edema, pleural effusions, or ascites, and lack of fever or other systemic symptoms. Monitoring of weight gain with early initiation of diuretics may be helpful in limiting more severe consequences of volume overload. Recognition that this syndrome can be mitigated by pretreatment with corticosteroids has led to inclusion of pretreatment with dexamethasone in many protocols.
- Paclitaxel infusion is associated with a high incidence (up to 30%) of acute hypersensitivity reactions with symptoms including dyspnea, bronchospasm, urticaria, and hypotension. Docetaxel has a

TABLE 64-6 Miscellaneous Chemotherapeutic Agents

Drug	Pulmonary Syndrome	Treatment	Comments
Paclitaxel	• Dyspnea, bronchospasm	• Decrease infusion rate • Corticosteroids and/or histamine antagonists	• Pretreatment with histamine antagonists and/or corticosteroids reduces incidence
	• Interstitial pneumonitis	• Discontinue drug	• Tends to occur within days to weeks after administration of drug
Docetaxel	• Pleural effusions • Noncardiogenic pulmonary edema	• Discontinue drug; diuretics • Supportive care	• Pretreatment with corticosteroids may decrease incidence
	• Interstitial pneumonitis	• Discontinue drug	
Vinca alkaloids	• Noncardiogenic pulmonary edema • Interstitial pneumonitis • Bronchospasm	• Discontinue drug • Corticosteroids	• Risk factor: concurrent treatment with mitomycin-C
All-*trans* retinoic acid	• “Differentiation syndrome”	• Corticosteroids • Discontinue drug	• Treatment regimens for acute promyelocytic leukemia using all-*trans* retinoic acid should include corticosteroids

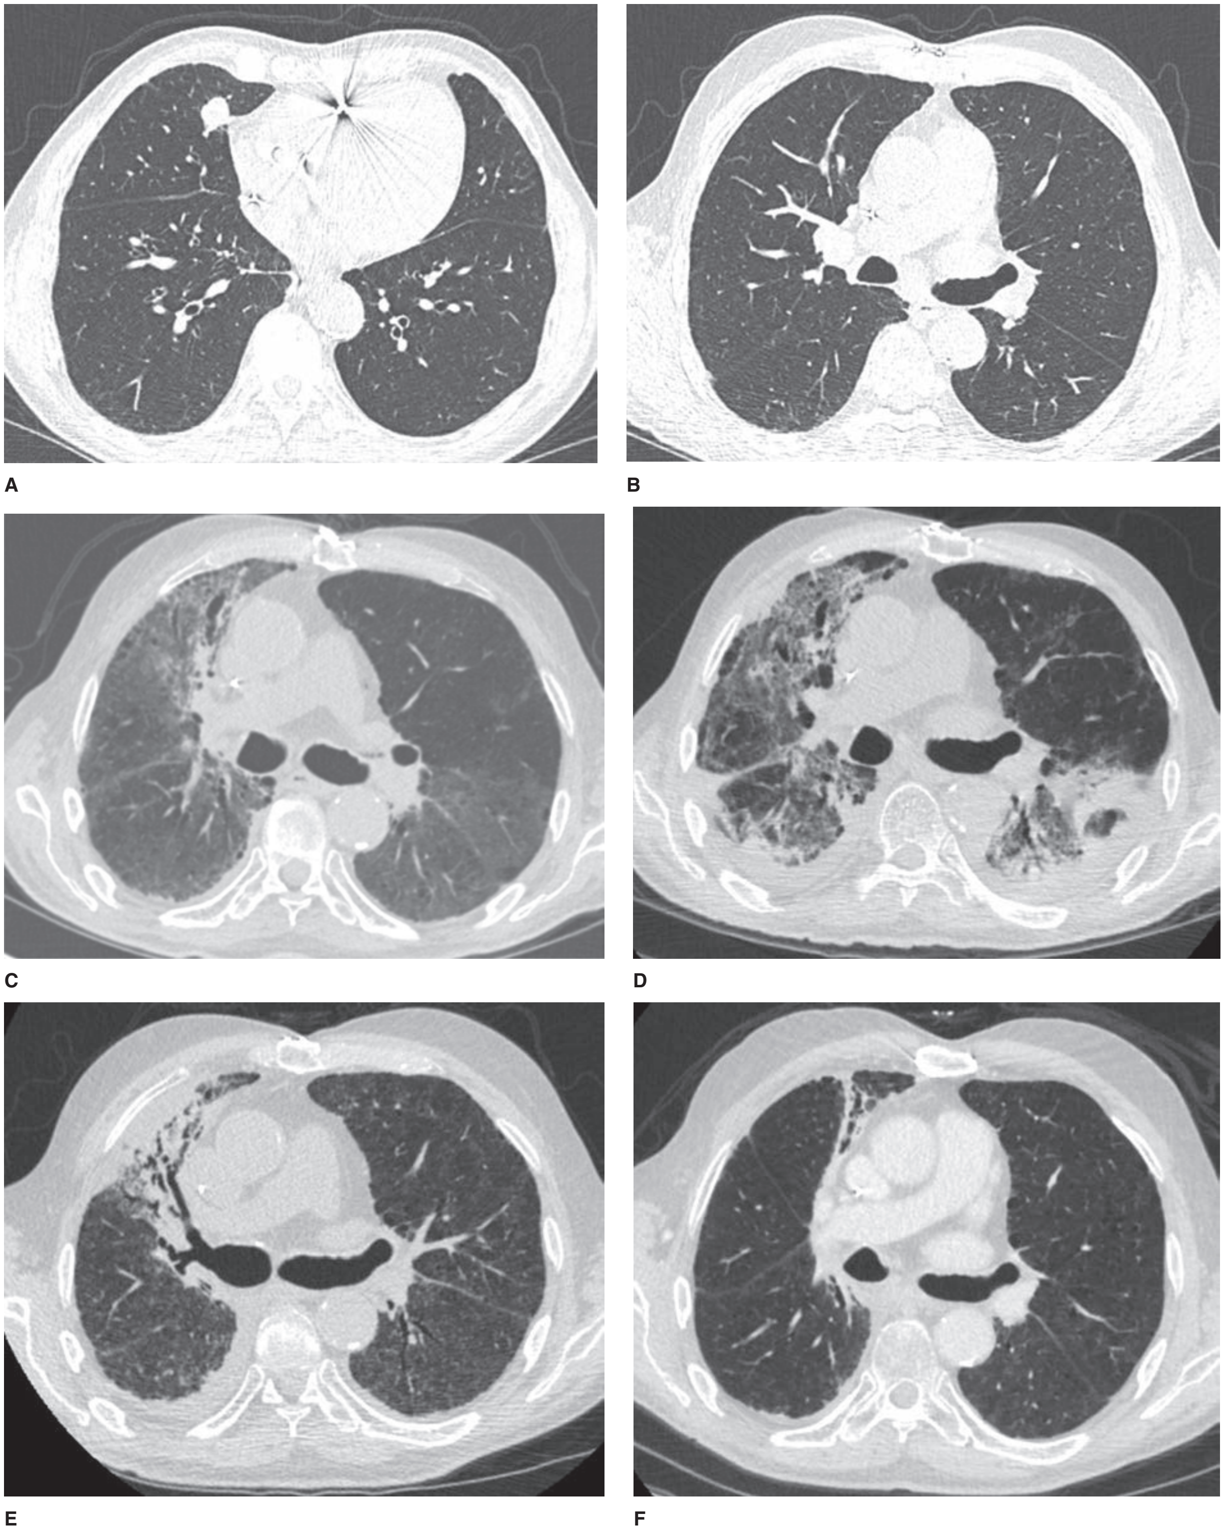

Figure 64-5 Serial chest computed tomography (CT) images of a 74-year-old man with T1N2M0, stage IIIA adenocarcinoma of the lung treated with four cycles of chemotherapy (carboplatin/paclitaxel) and concurrent radiation therapy. **A.** Representative image prior to treatment. The primary tumor was a 2.5-cm, solid, spiculated nodule in the right middle lobe. **B.** Representative image prior to treatment, approximately 1 cm inferior to the main carina. Tumor involved multiple mediastinal lymph node stations, including the subcarinal nodes. **C.** Representative image at the same level as **B**, at completion of concurrent chemoradiation. There are postradiation changes in the right middle lobe, as well as interstitial infiltrates in the right middle, right lower, and left lower lobes. **D.** Representative image at the same level as B, 6 weeks after completion of chemoradiation, demonstrating worsening of infiltrates in the affected lobes. The patient had developed cough and exertional dyspnea and a requirement for supplemental oxygen. Bronchoscopy showed no evidence of tumor or infection. The patient was felt to have paclitaxel-related pulmonary toxicity; corticosteroids were initiated. **E.** Representative image at the same level as **B**, 8 months after completion of chemoradiation and on a slowly tapering course of corticosteroids, demonstrating improvement but with residual right middle lobe infiltrate and bronchiectasis, and areas of pleural thickening. **F.** Representative image at the same level as B, 2 years after completion of chemoradiation, demonstrating residual postradiation changes in the right middle lobe and mild posterior pleural scarring.

much lower incidence of this type of acute complication.[107,117,118,121] Decreasing the infusion rate and/or administration of corticosteroids and histamine antagonists greatly reduces the frequency of this reaction to 1% to 2%.

Vinca Alkaloids

Vinca alkaloids given as sole agents are rarely associated with pulmonary toxicity. However, the combination of vinblastine, vindesine, or vinorelbine with mitomycin C has been reported to be associated with noncardiogenic pulmonary edema, interstitial pneumonitis, and bronchospasm, often in conjunction with more diffuse endothelial dysfunction (see earlier section on mitomycin C).[35] Vinorelbine as a sole agent has been associated with dyspnea in less than 5% of cases; it occurs within hours of dosing and generally responds to bronchodilators and corticosteroids.[122] Respiratory distress with pulmonary edema and interstitial pneumonitis also has been rarely described.

All-*trans* Retinoic Acid

All-*trans* retinoic acid (ATRA) is a vitamin A derivative used to treat acute promyelocytic leukemia (APL). Activity of ATRA occurs through its induction of maturation of malignant cells into mature neutrophils. A constellation of symptoms and signs known as “differentiation (retinoic acid) syndrome,” characterized by fever, weight gain from volume overload, respiratory distress with interstitial or alveolar infiltrates, pleural or pericardial effusions, hemodynamic instability, and renal insufficiency may occur from 2 to 21 days after drug initiation.[123,124] Pulmonary alveolar hemorrhage has been described as a rare complication.[125] The syndrome is frequently, although not universally, seen coincident with the development of a pronounced leukocytosis.[126] Radiographic features of differentiation syndrome include pleural effusions, cardiomegaly, interstitial edema, and widened vascular pedicle. Less frequently seen are prominent septal lines, nodules, ground-glass opacities, or parenchymal consolidation with air bronchograms. In the setting of diffuse alveolar hemorrhage, high-resolution chest CT demonstrates poorly defined centrilobular nodules and diffuse ground-glass opacification. Histologic examination most commonly reveals infiltration of the lung parenchyma with maturing myeloid cells, with or without pulmonary hemorrhage. Fibrinoid necrosis and pulmonary capillaritis also have been described. The syndrome is thought to result from endothelial damage resulting in edema, hemorrhage, fibrinous exudates, and infiltration of neutrophils.

The mechanism of ATRA-mediated pulmonary toxicity is poorly understood but is thought to reflect systemic release of inflammatory cytokines.[127] Increased expression of cell adhesion molecules on leukemic cells has been demonstrated after ATRA administration, as has increased endothelial expression of intracellular adhesion molecule 1 (ICAM-1) and vascular cell adhesion molecule 1 (VCAM-1). In addition, elevated levels of interleukin 1β (IL-1β), IL-6, and TNF-α have been observed and may promote leukocyte activation, contributing to tissue injury.

The incidence of differentiation syndrome is reported variably between 5% and 27%, with mortality among affected patients between 5% and 29%.[123,126,128,129,132,134] Prompt initiation of corticosteroids may be associated with improved outcome. Continuation of ATRA does not appear to be absolutely contraindicated, as long as corticosteroids are administered in a timely fashion. In cases with severe toxicity, discontinuation of ATRA is reasonable but does not necessarily preclude rechallenge with drug, given its known effectiveness in APL.

MOLECULARLY TARGETED AGENTS

There has been tremendous development of molecularly targeted chemotherapeutic agents over the past decade. Several classes of molecularly targeted chemotherapeutic agents exist including small molecule kinase inhibitors, monoclonal antibodies, and checkpoint inhibitors. Examples of molecularly targeted agents include epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors, BCR-Abl tyrosine kinase inhibitors, anaplastic lymphoma kinase (ALK) inhibitors, vascular endothelial growth factor (VEGF) inhibitors, MEK inhibitors, MET inhibitors, RET inhibitors, cyclin-dependent kinase inhibitors, and PI3K inhibitors (Tables 64-7 and 64-8).

■ EGFR Tyrosine Kinase Inhibitors

Small molecule inhibitors of the EGFR tyrosine kinase (EGFR TKI) were the first successful molecularly targeted agents effective for patients with NSCLC and virtually revolutionized the

TABLE 64-7 **Molecularly Targeted Agents: Tyrosine Kinase Inhibitors**

Drug	Pulmonary Syndrome	Treatment	Comments
EGFR TKI			
Gefitinib	• Interstitial lung disease • Pulmonary fibrosis	• Discontinue drug	• Develops within 3 months • Risk factors: elderly, cigarette smoking, pre-existing lung disease, Asian ethnicity
Erlotinib	• Interstitial lung disease	• Discontinue drug	• Risk factors: pre-existing lung disease
Afatinib	• Interstitial lung disease	• Discontinue drug	• Also inhibits HER2 • Risk factors: elderly
Osimertinib	• Interstitial lung disease	• Discontinue drug	• T90M mutation specific • Risk augmented with anti–PDL-1 therapy
BCR-Abl TKI			
Imatinib	• Pleural effusions	• Diuretics	
	• Interstitial lung disease	• Discontinue drug • Corticosteroids	• Risk factors: pre-existing interstitial lung disease
Dasatinib	• Pleural effusions	• Diuretics • Drug interruption	• Incidence much higher than imatinib
	• Pulmonary arterial hypertension	• Discontinue drug • Consider PAH therapy	

(continued)

TABLE 64-7 Molecularly Targeted Agents: Tyrosine Kinase Inhibitors *(Continued)*

Drug	Pulmonary Syndrome	Treatment	Comments
ALK TKI			
Crizotinib Ceritinib Alectinib	• Interstitial lung disease	• Discontinue drug	• Develops within 3 months
Brigatinib	• Interstitial lung disease	• Drug interruption • Consider rechallenge	• Develops acutely within 1 week
MET inhibitor			
Capmatinib	• Interstitial lung disease	• Discontinue drug	• Develops within 1–2 months
RET inhibitor			
Pralsetinib	• Interstitial lung disease	• Discontinue drug	
Selpercatinib	• Interstitial lung disease	• Disrupt drug • Discontinue drug if severe	• Less frequent than pralsetinib
VEGF TKI			
Sunitinib	• Dyspnea • Cough	• Supportive care	
Sorafenib	• Dyspnea • Cough • Interstitial lung disease	• Drug discontinuation	• ILD very rare but extremely fatal • Drug should be stopped with any pulmonary side effects
Pazopanib	• Pneumothorax	• Supportive care	• Risk factors: subpleural disease

approach to treatment of this group of patients (Fig. 64-6). There are now six EGFR tyrosine kinase inhibitors, including gefitinib, erlotinib, afatinib, osimertinib, lapatinib, and dacomitinib. Lung toxicity associated with lapatinib and dacomitinib is very rare. A study of the remaining EGFR TKIs indicated a 1.12% incidence of all grades of pneumonitis in more than 15,000 patients treated.[129] However, the most common cause of drug associated fatality is pneumonitis.[130]

Gefitinib was the first EGFR tyrosine kinase inhibitor available for clinical use. In a prospective study involving more than 3000 patients treated with gefitinib for NSCLC in Japan, 4% of patients developed interstitial lung disease by 12 weeks of treatment with

TABLE 64-8 Molecularly Targeted Agents: Other Kinase Inhibitors

Drug	Pulmonary Syndrome	Treatment	Comments
MEK inhibitor			
Trametinib	• Interstitial lung disease	• Discontinue drug	
Encorafenib + binimetinib	• Interstitial lung disease	• Drug disruption • Consider dose reduction or discontinuation	• Rechallenge based on severity of pneumonitis
	• Venous thromboembolism	• Drug disruption • Consider dose reduction or discontinuation	• Rechallenge based on severity
Cyclin dependent kinase inhibitors			
Palbociclib Ribociclib Abemaciclib	• Interstitial lung disease	• Drug disruption • Discontinue drug if severe	• Very low incidence in clinical trials, but with reports of severe pneumonitis emerging
PI3K inhibitors			
Idelalisib	• Interstitial lung disease	• Drug disruption • Corticosteroids	• Rechallenge based on severity of pneumonitis
	• Pulmonary infection	• Targeted to infection	
Copanlisib Duvelisib	• Interstitial lung disease	• Drug disruption • Corticosteroids	• Rechallenge based on severity of pneumonitis
	• Pulmonary infection	• Targeted to infection	• *Pneumocystis jirovecii* infection common, prophylaxis recommended
Alpelisib	• Interstitial lung disease	• Discontinue drug	

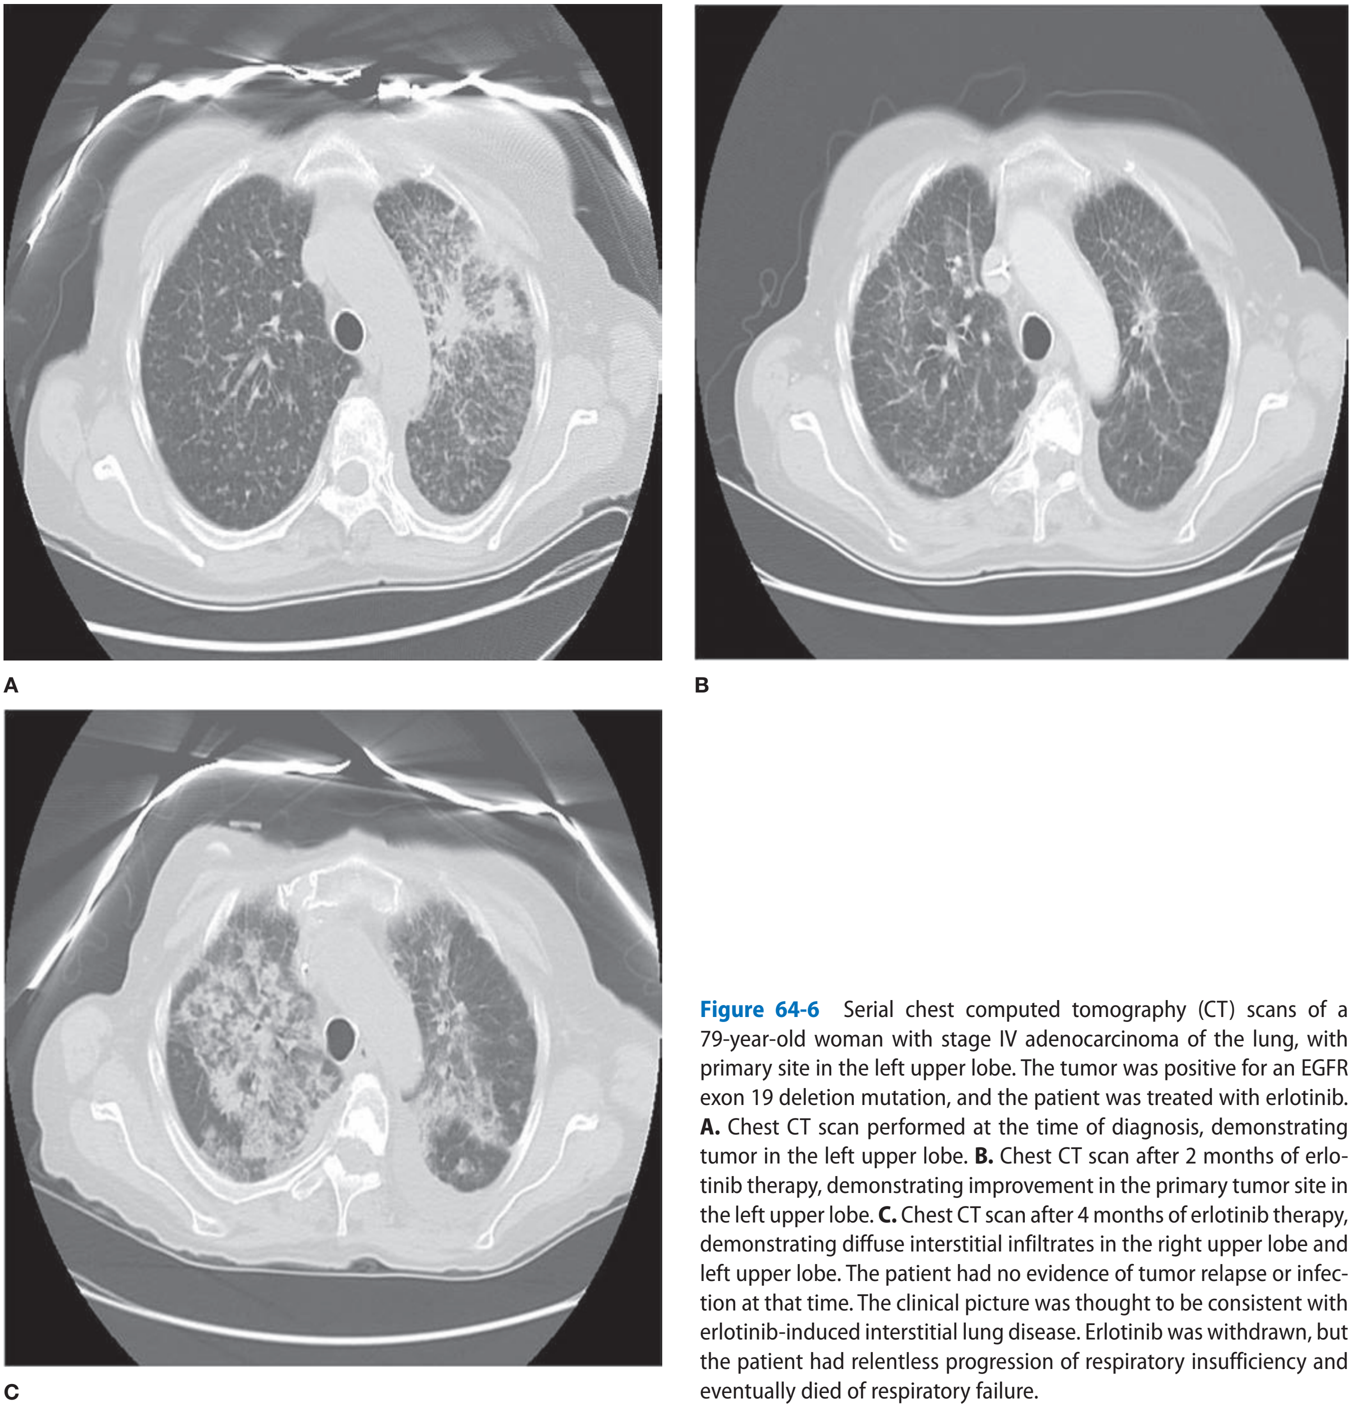

Figure 64-6 Serial chest computed tomography (CT) scans of a 79-year-old woman with stage IV adenocarcinoma of the lung, with primary site in the left upper lobe. The tumor was positive for an EGFR exon 19 deletion mutation, and the patient was treated with erlotinib. **A.** Chest CT scan performed at the time of diagnosis, demonstrating tumor in the left upper lobe. **B.** Chest CT scan after 2 months of erlotinib therapy, demonstrating improvement in the primary tumor site in the left upper lobe. **C.** Chest CT scan after 4 months of erlotinib therapy, demonstrating diffuse interstitial infiltrates in the right upper lobe and left upper lobe. The patient had no evidence of tumor relapse or infection at that time. The clinical picture was thought to be consistent with erlotinib-induced interstitial lung disease. Erlotinib was withdrawn, but the patient had relentless progression of respiratory insufficiency and eventually died of respiratory failure.

gefitinib, compared with 2.1% of patients treated with cytotoxic chemotherapy.[131] Studies done around the world have noted that pulmonary toxicity appears to vary geographically and is seen more commonly in Asian, as opposed to Caucasian or African, populations.[132–134] Toxicity typically occurs early in the course of treatment, with median exposure from 24 to 42 days. Withdrawal of drug appears in most cases to be helpful, but inexorable progression to end-stage respiratory failure and death occurs in approximately 31% of patients with gefitinib-induced pulmonary toxicity. Histologic evaluation of fatal pneumonitis demonstrated diffuse alveolar damage. Risk factors associated with a higher likelihood of developing toxicity include male sex, older age, cigarette smoking, pre-existing interstitial lung disease, and poor performance status.[131,134,135]

The mechanism of gefitinib-induced lung injury remains a subject of investigation. EGFR is known to be upregulated in response to lung injury and may be important in promoting type II pneumocyte hyperplasia in response to injury. In murine models gefitinib leads to more severe lung fibrosis in animals exposed to bleomycin. The increased frequency of this toxicity in patients with pre-existing pulmonary fibrosis lends credence to the hypothesis that gefitinib impairs the regeneration of alveolar epithelial cells in response to injury.

Erlotinib is the EGFR tyrosine kinase inhibitor used most commonly in the United States, as gefitinib is not available for clinical treatment purposes.[77,136,137] The overall incidence of pneumonitis associated with erlotinib is likely lower compared to gefitinib, which may reflect geography, as erlotinib has predominantly been used outside of Asia. In an elderly Japanese cohort of more than 9000 patients treated with erlotinib, the incidence of all grades of pneumonitis was 4.2% with a mortality rate of 1.7%, which is similar to a predominantly Japanese cohort treated with gefitinib (3.5% incidence and

1.6% mortality).[135,138] In a U.S. study predominantly of Caucasians on erlotinib plus standard chemotherapy versus chemotherapy alone, the incidence of interstitial lung disease in the erlotinib group was 1% versus 0.2% in the placebo group.[139] Three cases in the erlotinib arm were fatal and were directly attributed to the drug.[140] The time course of lung injury appears to be similar to gefitinib, with appearance of pulmonary injury occurring within weeks of initiation of treatment. The presence of underlying interstitial lung disease appears to be a risk factor for development of drug toxicity.[141]

Afatinib is a small molecule that inhibits both EGFR and human epidermal growth factor 2 (HER2) receptors. Similar to erlotinib, initial studies of safety indicated low incidence of grade 3 or higher pneumonitis ranging from 0.4% to 1%.[142,143] However, this risk may be significantly increased in the elderly population, as a study of 40 patients with a mean age of 77 demonstrated a risk of grade 3 or higher pneumonitis 7.5% with 2 deaths due to pneumonitis-associated respiratory failure.[144]

Osimertinib is a newer-generation EGFR TKI used in the treatment of patients with EGFR T790M mutation NSCLC who have progressed after treatment with conventional EGFR TKI therapy. It confers a 3% risk of pulmonary toxicity, although mortality rates are lower compared to gefitinib.[145,146] As with similar agents, toxicity generally presents within the first 3 months of therapy, manifests as nonspecific pulmonary symptoms, and typically resolves with discontinuation of drug.

Recently there has been interest in combining EGFR targeted therapy with immune checkpoint therapy, specifically anti–PDL-1 treatments (discussed below). However, this approach has been shown to have a significantly higher incidence of significant pneumonitis (25.7% vs. 4.59%).[147] This risk is predominantly when anti–PDL-1 therapy is swiftly followed by EGFR TKI therapy and possibly only limited to osimertinib rather than early-generation EGFR TKIs.[148–150]

■ BCR-Abl Tyrosine Kinase Inhibitors

Imatinib was the first clinically available and prototypic molecularly targeted therapy. Developed in the 1990s, it is a small molecule tyrosine kinase inhibitor that suppresses proliferation of cells expressing the BCR-Abl fusion protein. The fusion gene created by translocation of the Abl-1 ("Abelson") gene on chromosome 9 to a part of the "breakpoint cluster region" (BCR) gene on chromosome 22 is the "Philadelphia chromosome," a hallmark for CML. Imatinib is used for treatment of patients with CML as well as gastrointestinal stromal tumors.

The most common pulmonary complication related to administration of imatinib is the development of pleural effusions. This reflects the propensity of patients receiving imatinib to retain fluid in various anatomic compartments. The incidence of pleural effusions is rather low, affecting only 0.8% over the course of 5 years of treatment.[151] Less commonly, imatinib has been associated with the development of interstitial lung disease; underlying fibrotic lung disease may be a predisposing factor.[152] In small series, corticosteroids have been reported as potentially beneficial; rechallenge is generally not recommended but has been reported without recurrent lung disease.

Almost inevitably, tumor resistance to the small molecule tyrosine kinase inhibitors occurs, due to development of new point mutations in the tumor kinase, resulting in resistant clones of cells and relapse of disease. Second-generation BCR-Abl tyrosine kinase inhibitors include dasatinib, nilotinib, bosutinib, and ponatinib. Unlike imatinib, dasatinib-associated pleural effusions are very frequently reported. Over 5 years of treatment, the frequency of pleural effusions is up to 28%, with the highest incidence in the first year of use.[151] A dose-dependent frequency has been described.[153] Drug interruption and therapeutic thoracentesis are sometimes necessary for dyspnea. Like imatinib, dasatinib has been reported in case series to be associated with development of interstitial lung disease.[154,155]

Perhaps more concerning, there is increasing evidence of an association between the development of pulmonary arterial hypertension and dasatinib use.[156–158] Up to 5% of patients on dasatinib have elevated pulmonary pressures on transthoracic echocardiogram. In the largest cohort of 21 patients with PAH confirmed by right heart catheterization, 71% were female with a median age of 52.[159] All patients had the drug withheld, and half were treated with PAH-directed therapies. While the majority of patients had improvement in their symptoms and exercise capacity with these measures, 37% had persistent PAH despite drug discontinuation and/or PAH therapy indicating irreversible pulmonary arterial remodeling. Pulmonary hypertension has not been reported as a complication of imatinib.

Nilotinib, bosutinib, and ponatinib are newer and less widely used BCR-ABL inhibitors. The incidence of pleural effusion appears to be less frequent, and there are only case reports of other pulmonary toxicity including pneumonitis and PAH.

■ ALK Inhibitors

Crizotinib, ceritinib, alectinib, and brigatinib inhibit the ALK and have been useful in patients with NSCLC demonstrating the EML4-ALK fusion oncogene. Interstitial lung disease has been reported with crizotinib, ceritinib, and alectinib treatment.[160] Toxicity with these agents generally develops within 3 months of therapy; most cases resolve with discontinuation of drug and supportive care, although rare fatalities have been reported. In contrast, pneumonitis related to brigatinib presents acutely, typically within the first week of treatment. Some patients may be able to undergo successful rechallenge with brigatinib once pneumonitis completely resolves.[161] As these drugs are used only in a relatively small population of lung cancer patients with the specific targetable mutation, clinical information relating to potential lung injury is limited.

■ Other Small Molecule Inhibitors

Two classes of drugs are used to treat metastatic melanoma with BRAF mutations. These include inhibitors of the mitogen activated protein kinase (MEK) and direct BRAF inhibitors. The MEK inhibitor trametinib is associated with a 2% risk of interstitial lung disease.[162] Vemurafenib is a BRAF inhibitor with only case reports of pulmonary injury. Encorafenib plus binimetinib is a BRAF plus MEK inhibitor. While it has a very low incidence of pneumonitis, venous thromboembolism and pulmonary embolism can be seen in 6% and 3%, respectively.[163]

A minority of patients with NSCLC have mutations in the mesenchymal-epithelial transition (MET) gene, rearranged during transfection (RET) gene, or c-Ros oncogene 1 (ROS1). Capmatinib, a MET inhibitor, causes pneumonitis in up to 4.5% of patients (1.8% grade 3 or above).[164] Additionally, 4% of patients had grade 3 pleural effusions. In initial trials, pralsetinib, a RET inhibitor, had a high incidence of interstitial lung disease (10% total, 2.7% grade 3–4, 0.5% fatal).[165] Selpercatinib, a second RET inhibitor, has a much lower incidence of interstitial lung disease (<2%), with no reports of grade 3 or higher pneumonitis.[166] Entrectinib, a ROS1 inhibitor used in NSCLC and other solid tumors, causes pleural effusions in 10% of patients and respiratory failure in 2%.[167]

Inhibitors of the cyclin-dependent kinases (CD4/6) include palbociclib, ribociclib, and abemaciclib and are used to treat hormone receptor–negative, HER-2 negative breast cancer. A very low incidence of pulmonary toxicity was noted in initial trials involving these drugs, but with increasing use, case reports of severe pneumonitis have emerged. A postmarketing FDA warning has since been issued.[168]

There are four available phosphoinositide 3-kinase (PI3K) inhibitors available for use with varying risk profiles. Idelalisib, which is approved for chronic lymphocytic leukemia, follicular lymphoma, and small lymphocytic leukemia, is associated with an 11% risk of both infectious and noninfectious pneumonia, with 7% being grade

TABLE 64-9 Monoclonal Antibodies

Drug	Pulmonary Syndrome	Treatment	Comments
Bevacizumab	• Pulmonary hemorrhage	• Supportive care • Discontinue drug	• Risk factors: cavitary tumor, squamous cell histology
	• Tracheoesophageal fistula	• Supportive care	• Risk factors: mediastinal radiation
Cetuximab Panitumumab	• Bronchospasm, stridor	• Supportive care • Corticosteroids • Discontinue drug	• May occur during infusion • Risk factors: asthma, atopy, history of allergic reactions

3 or higher.[169] In a pooled study of 168 patients receiving copanlisib, the incidence of grade 3 to 4 lower respiratory tract infections was 13% (including *Pneumocystis jirovecii*) and pneumonitis 5%.[170] A similar rate of both infectious and noninfectious pneumonitis has been observed with duvelisib use. Alpelisib, used to treat hormone receptor–positive, HER2-negative breast cancer with a PI3K mutation has a <2% incidence of pneumonitis.[171]

■ VEGF Inhibitors

There are three main classes of inhibitors of VEGF, which include monoclonal antibodies, small molecule TKIs, and a fusion molecule inhibitor. The latter has no known pulmonary adverse events.

Bevacizumab is a monoclonal antibody directed against VEGF with activity against breast, colon, renal, and NSCL cancers (Table 64-9). Improved response rates for locally advanced and metastatic NSCLC are observed when bevacizumab is added to traditional chemotherapy.[172] In a series including 99 patients with newly diagnosed stage IIIB or IV or recurrent NSCLC, six patients developed serious bleeding complications including hemoptysis or hematemesis.[173] Four of the six patients died as a result of the hemorrhage. All six cases of hemorrhage appeared to be tumor related, with four of the six patients having squamous cell histology. Radiographically visible cavitation or necrosis was seen in five of the six cases of hemorrhage. As a result, current clinical investigations of regimens including bevacizumab generally exclude patients with cavitary pulmonary disease or squamous cell histology. Additionally, when combined with mediastinal radiation, there is a significant incidence of tracheoesophageal fistula formation.[174]

Sunitinib, sorafenib, and pazopanib are the three approved VEGF TKIs. Sunitinib has been reported to cause grade 3 to 4 cough and dyspnea in 13% and 19% of patients, respectively.[175] Sorafenib has a very low incidence of pneumonitis (0.44%); however, when present, the case fatality rate is high (41%).[176] Pazopanib is used primarily in the treatment of soft tissue sarcomas and renal cell carcinomas. In the phase 3 trial of pazopanib in soft tissue sarcomas, the incidence of pneumothorax was 3%, which was similar to the previously reported rate of spontaneous pneumothorax in this patient population.[177,178] Reports of incidence of up to 14% was reported at a single center, exclusively in patients with subpleural or pleural metastases.[179]

■ Other Monoclonal Antibodies

Monoclonal antibodies have been increasingly employed to treat a variety of malignancies (Table 64-9). Pulmonary toxicity has been reported with their use.

EGFR Antibodies

Cetuximab and panitumumab are chimeric monoclonal antibodies directed against EGFR. Infusion of cetuximab may be associated with symptoms suggestive of anaphylaxis, including bronchospasm or stridor. In severe cases, respiratory compromise may be life-threatening. Risk factors for the development of these complications include a history of asthma, atopy, or allergic reactions.[180,181] Similar reactions have been observed less frequently during infusion of panitumumab.[182] The incidence of pneumonitis is low in patients treated with either cetuximab or panitumumab.[183,184]

Rituhximab

Rituximab is a chimeric monoclonal antibody directed against the CD-20 antigen on B lymphocytes; it has demonstrated activity against non-Hodgkin lymphoma. It is increasingly used in inflammatory processes, including connective tissue diseases, autoimmune disorders, and solid organ transplantation. Like cetuximab, rituximab can be associated with infusion reactions, which, in severe form, may include bronchospasm and angioedema. Pulmonary parenchymal toxicity, while rare, is well described.[185–187] In one series of 107 patients with NHL receiving a regimen including rituximab, 9 of 107 patients developed interstitial pneumonitis associated with fever, dyspnea, and cough.[187] Treatment with glucocorticoids resulted in improvement. Re-treatment was attempted in four patients, two of whom developed recurrence of interstitial disease; therefore, rechallenge is usually not recommended.

The clinical syndrome of rituximab-induced pulmonary toxicity typically begins insidiously with cough and dyspnea, which may progress with subsequent re-exposure to rituximab. Development of hypoxemia in association with parenchymal ground-glass opacification on CT scan has been noted. Histologic examinations have revealed reactions typical of cryptogenic organizing pneumonia/bronchiolitis obliterans organizing pneumonia, as well as interstitial inflammation with T lymphocytes and extensive arterial thrombosis. While fatal outcomes have been reported, generally this entity has responded well to withdrawal of rituximab and administration of corticosteroids.

Trastuzumab

Trastuzumab is a humanized monoclonal antibody directed against the HER2 protein expressed by some breast and gastroesophageal tumors. Infusion reactions with trastuzumab are common; in severe cases, symptoms may include bronchospasm and hemodynamic instability. Rarely, patients with breast cancer receiving trastuzumab may develop acute pulmonary toxicity, with interstitial pneumonitis, organizing pneumonia, or acute respiratory distress syndrome; in some cases, glucocorticoids have been used successfully.[188,189]

Trastuzumab can be given combined with other cytotoxic drugs as conjugates in patients with breast cancer previously treated with trastuzumab and taxanes. Ado-trastuzumab emtansine (combined with cytotoxic microtubule inhibitor DM1) rarely causes acute pneumonitis (1.2%).[190] Fam-trastuzumab deruxtecan (combined with cytotoxic topoisomerase 1 inhibitor), conversely, has a high incidence of pneumonitis (14%), with fatality reported as 2.2%.[191]

IMMUNOTHERAPIES

A variety of immunotherapies for cancer have been associated with lung toxicity and are described below.

AL GRAWANY

Checkpoint Inhibitor Immunotherapies

Immunomodulatory antibodies directed against the programmed cell death 1 (PD-1) receptor (pembrolizumab and nivolumab), the PD-1 ligand (PD-L1, e.g., atezolizumab, durvalumab, and avelumab), and the cytotoxic T lymphocyte–associated antigen 4 (CTLA-4, e.g., ipilimumab) have altered the landscape of oncologic therapy. These agents are used to treat an increasing variety of advanced stage malignancies including NSCLC, melanoma, renal cell carcinoma, head and neck cancer, urothelial cancer, Hodgkin lymphoma, cutaneous squamous cell carcinoma, and Merkel cell carcinoma.

Checkpoint immunotherapies function by restoring or augmenting intrinsic antitumor immune responses that cancer cells adapt to evade. As a result of their unique mechanisms, these agents are associated with a spectrum of adverse events, including pulmonary toxicity, that reflect unintended dysregulation of immune responses throughout the body. Although pneumonitis is a relatively infrequent event compared with other immune-related complications, it is among the most serious and may be fatal if unrecognized and untreated.

The incidence of pneumonitis appears to be higher with anti–PD-1 monotherapy compared with anti–CTLA-4 monotherapy. In a meta-analysis of nearly 4500 clinical trial patients with melanoma, NSCLC, and renal cell carcinoma, the incidence of all-grade pneumonitis was 3% for anti–PD-1 monotherapy, with severe toxicity observed in <1% of patients. However, rates of toxicity more than doubled when anti–PD-1 therapy was given in combination with anti–CTLA-4 therapy.[192] Moreover, outside the clinical trial setting, rates of pulmonary complications observed in clinical practice have been significantly higher. A single-center retrospective study of 205 patients with NSCLC treated with anti–PD-1/PD-L1 therapy either as part of a clinical trial or as standard of care reported pneumonitis in 19%.[193] In a multicenter series of 915 patients, the overall rate of pneumonitis was 5% for those receiving monotherapy, and it rose to 10% for those receiving anti–PD-1/PD-L1 therapy in combination with anti–CTLA-4 therapy.[194] This same series described considerable variability in the presentation of pulmonary toxicity associated with checkpoint inhibitors. Though most cases present after 2 to 3 months of therapy, time to onset ranged from 9 days to 19.2 months. Indeed, cases of immunotherapy-related pneumonitis have been reported after drug discontinuation.

As with conventional chemotherapy-related pulmonary toxicity, clinical presentation is typically nonspecific, with cough and dyspnea as the most common features. Fever and chest pain are rarely reported. Immunotherapy-related toxicities may affect any organ system, with some patients experiencing multiple toxicities over the course of therapy or even simultaneously. In a multicenter retrospective study of 623 patients on anti–PD-1/PD-L1 therapy, pneumonitis was most commonly observed in coincidence with thyroiditis and dermatitis.[195] However, history of any prior nonpulmonary immunotherapy-related adverse event, including rash, endocrinopathy, arthralgia, or colitis, should raise the index of suspicion for immunotherapy-related pneumonitis.

There are no pathognomonic radiographic or pathologic findings. In fact, radiographic presentation varies greatly and may include interstitial changes, ground-glass opacities, focal infiltrate/cryptogenic pneumonia-like, or hypersensitivity pneumonitis-like patterns (Fig. 64-7).[196] Sarcoid-like presentations with hilar

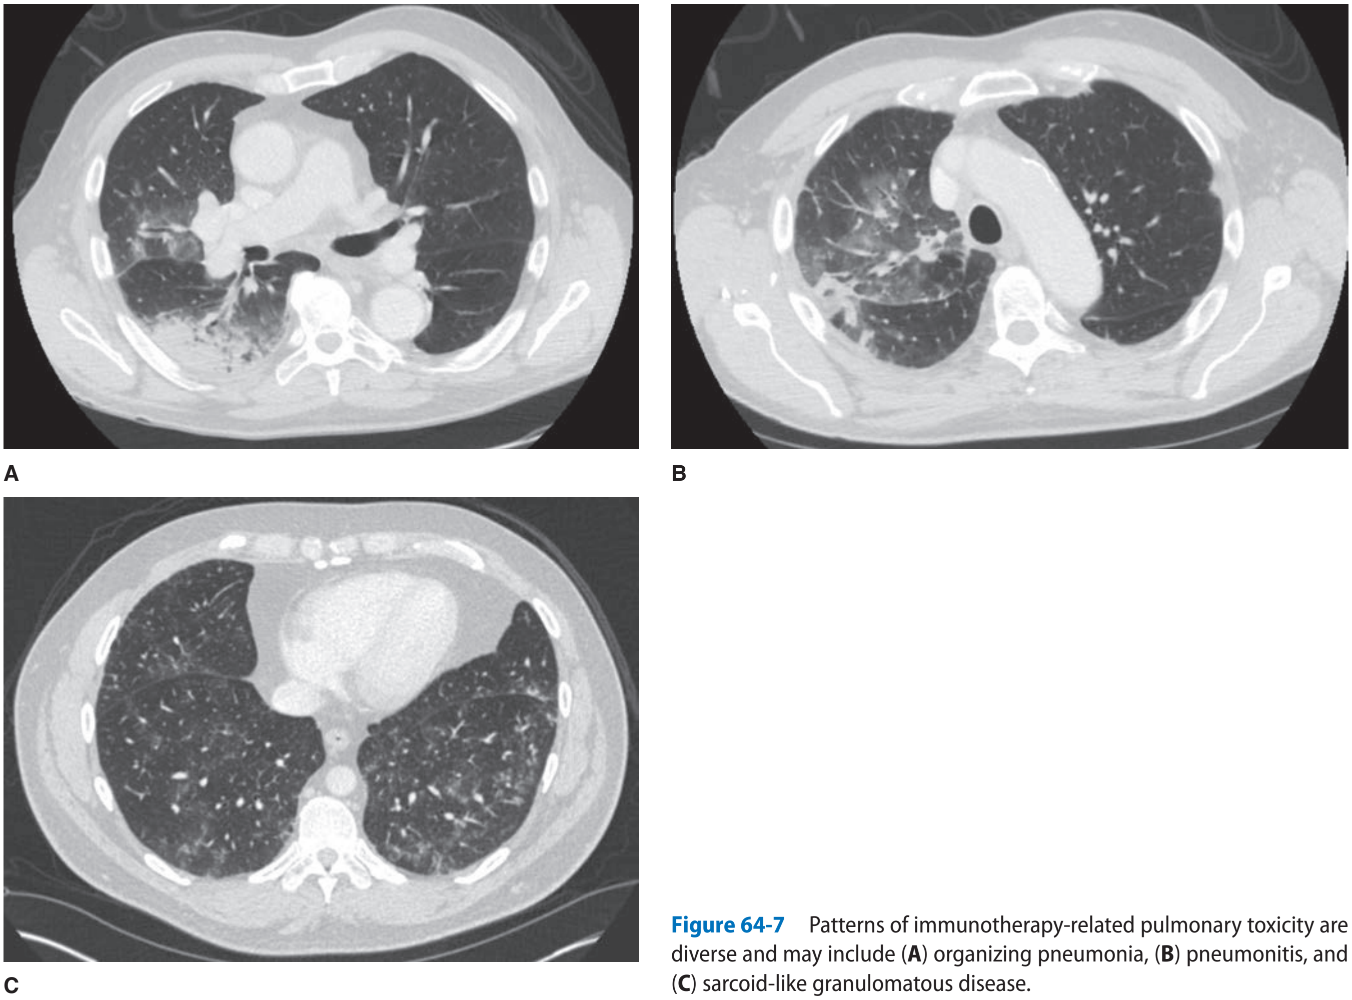

Figure 64-7 Patterns of immunotherapy-related pulmonary toxicity are diverse and may include (**A**) organizing pneumonia, (**B**) pneumonitis, and (**C**) sarcoid-like granulomatous disease.

adenopathy and nodules also have been described. Pathologic findings are similarly variable and reflective of the typical patterns associated with the radiographic presentations described above. Thus far, there are no reliable serologic biomarkers to assist in the diagnosis of suspected immunotherapy-related pulmonary toxicity; similarly, PD-L1 expression in the tumor milieu does not appear to correlate with rates of observed toxicity.

There are no prospective clinical trials describing optimal treatment; therefore aggregate anecdotal experience presently guides management and is based on clinical severity.[197,198] Asymptomatic patients with new radiographic abnormalities may be closely observed for 2 to 4 weeks while immunotherapy is held; if symptoms develop or radiographic findings progress, systemic corticosteroid therapy should be considered. The risk/benefit balance of re-challenge with further immunotherapy after mild toxicity can be approached on a case-by-case basis. In the case of symptomatic individuals, consensus experience favors the use of oral or IV systemic corticosteroids (1–2 mg/kg/d of prednisone or equivalent) tapered over several weeks. In refractory cases, additional immunosuppression with infliximab, azathioprine, mycophenolate mofetil, or cyclophosphamide has been utilized, but the impact on survival remains uncertain.[194,199,200] The majority of patients will improve with either drug cessation or the use of systemic corticosteroids, but clinical relapses after cessation of corticosteroids have been reported and may require protracted immunosuppressive therapy. Fulminant and refractory cases of pulmonary toxicity have led to rare fatalities, although attribution may be confounded by opportunistic infections in immunosuppressed individuals or progression of underlying malignancy. While concerns have been raised about the impact of immunosuppression on antitumor response, as of yet there is no evidence that treating immunotherapy-related pulmonary toxicity negatively impacts survival or the durability of the treatment response.[201]

■ Chimeric Antigen Receptor (CAR)–T Cell Therapy

Chimeric antigen receptor (CAR)–T cell therapy has recently been used to treat acute lymphoblastic leukemia (ALL) and refractory lymphomas. The treatment uses the patient's own T lymphocytes transduced with a gene encoding a CAR to direct the patient's T cells against the malignant cells. The most common pulmonary toxicity is associated with cytokine release syndrome (CRS) and is characterized by hypoxemia, tachypnea, pleural effusions, and pulmonary edema (Table 64-10). CRS is more common with bulky disease (especially seen in ALL), high infusion dose, and certain lymphodepletion regimens. Commonly, CRS beings 1 to 14 days after therapy. Grade 3 to 4 CRS is treated with a combination of tocilizumab (IL-6 receptor antagonist) and steroids.

Pulmonary infectious complications are not uncommon following CAR–T cell therapy. Infectious complications can be related to prior cytopenias or due to immunosuppressive mediations used to treat CRS. In one case series, 42% of patients with B-cell leukemia developed pulmonary infection with an associated mortality rate of 6%. Grade 3 or greater CRS was independently associated with pulmonary infection.[202]

■ Interleukin 2

Interleukin 2 (IL-2) is a glycoprotein secreted by activated lymphocytes. IL-2 therapy alone, or in conjunction with lymphokine-activated killer (LAK) cells, has proved beneficial in patients with metastatic renal cell carcinoma or melanoma. In the current era of checkpoint inhibitor immunotherapy approaches, it is generally not the first treatment of choice, but it is an option for patients with disease progressing through immunotherapy-focused regimens.

Pulmonary complications related to IL-2 largely relate to cardiovascular instability with a vascular leak syndrome. This can result in cardiogenic, as well as noncardiogenic, pulmonary edema and may be associated with hypotension, renal insufficiency, and pleural effusions.[203] Several mechanisms have been identified that may explain the increase in capillary permeability.[204,205] IL-2–activated lymphocytes produce a variety of cytokines, including tumor necrosis factor (TNF) and IL-1. These may alter endothelial permeability and are thought to be important in the pathogenesis of other capillary leak syndromes, for example, in septic shock. IL-2 also may promote the adhesion of natural killer cells to the capillary endothelium, resulting in alteration of vascular integrity. IL-2 is also associated with toxicity in multiple other organs, including the heart. Therefore, IL-2–induced cardiac dysfunction may contribute to the development of pulmonary interstitial edema.

Inhalational IL-2 has also been studied in clinical trials to treat pulmonary metastases in patients, primarily with renal cell carcinoma and melanoma.[206–208] Bronchospasm has been reported, which can be mitigated by pretreatment with inhaled bronchodilator. The inhalational route of IL-2 appears to abrogate the risk of pulmonary toxicity, while demonstrating efficacy against intrapulmonary metastatic disease.

IL-2 appears to have a cumulative dose-dependent lung toxicity that seems to be compounded by LAK cell administration.[209,210] Lung toxicity does appear to be reversible. In most cases, clinical and radiographic abnormalities resolve within several days after cessation of therapy.

TABLE 64-10 Immunotherapies

Drug	Pulmonary Syndrome	Treatment	Comments
Checkpoint inhibitors	• Pneumonitis • Organizing pneumonia • Sarcoid-like toxicity	• Discontinue drug • Corticosteroids • Secondary immunosuppression for steroid-refractory toxicity	• Rechallenge based on severity • May persist or recur despite drug discontinuation • Risk factors: combination anti–PD-(L)1/anti–CTLA-4 therapy, preexisting ILD, prior thoracic radiotherapy, combination with EGFR TKI therapy, squamous NSCLC histology
Chimeric antigen receptor (CAR)–T cell therapy	• Cytokine release syndrome (CRS)	• Tocilizumab • Corticosteroids	• Begins 1–14 days post therapy
	• Pulmonary infection	• Targeted to infection	• Related to prior cytopenias and/or immunosuppressive regimen to treat CRS
Interleukin-2	• Cardiogenic edema • Pleural effusions	• Diuretics • Supportive care	• Vascular leak syndrome • Risk factors: cumulative dose, administration of LAK cells

CHAPTER 65

Drug-induced Pulmonary Disease Due to Nonchemotherapeutic Agents

Hilary C. Cain

INTRODUCTION

Medications have long been recognized as having the potential to cause pulmonary injury even when given at therapeutic doses. The precise incidence of drug-induced respiratory disease is difficult to ascertain and potentially is confounded by reporting bias for positive events; the signs and symptoms of lung toxicity are shared by many other pulmonary conditions and diseases. Data on adverse events are supplied to national databases such as the U.S. Food and Drug Administration Adverse Event Reporting System (FAERS) and the Japanese Adverse Event Report (JADER), and these databases can be utilized to determine patterns and incidence of events. However, these databases are limited by data input, and concerns inevitably are raised about the completeness and accuracy of direct submissions from providers and healthcare facilities compared with those from drug manufacturers.[1,2] As the categories and varieties of therapeutic drugs continue to increase, clinicians will encounter disease from new culprit drugs in addition to well-established drug reactions. A web-based data repository, Pneumotox V2.2 (*www.pneumotox.com*), is a useful tool for the clinician, as it provides frequent updates based on the emerging literature on drug-induced respiratory toxicities.

When the clinician-scientist explores the literature on drug-induced lung injury, it is critical to recognize that not all reported associations between medications, over-the-counter supplements or illegal drugs, and respiratory disease imply a definitive causal link between a specific drug and the injury pattern described. The literature needs to be cautiously interpreted before concluding that the reported associations are due to the implicated drug rather than a confluence of clinical conditions. This chapter addresses the principles that characterize drug-induced lung disease and examines some of the more common medications and drug classes that are implicated in pulmonary toxicity. Chemotherapeutic agents are discussed in a separate chapter 64.

GENERAL PRINCIPLES OF DRUG-INDUCED LUNG DISEASE

Drug-related pulmonary injury is a rare event. Reactions typically occur in a small minority of individuals exposed to a given agent. The incidence of drug- and radiation-induced interstitial disease was examined over a 12-year period (1997–2008) in a database of approximately 9 million patients from the United Kingdom, and an incidence of 0.8 per 1,000,000 patients per annum for drug-related interstitial disease was reported. Notably, this cohort was assembled before the utilization of many immunomodulatory and biologic therapies, and more recent data suggest a rate of drug-induced interstitial disease as high as 12.4 cases per million per year.[3] These data, however, reflect only a portion of the impact of drug-induced respiratory disease, because not only the interstitium is affected; the alveoli, upper and lower airways, pleura, pulmonary vasculature, muscles of respiration, and the central nervous system governing respiratory control are all susceptible to injury from ingested, inhaled, and parenterally administered agents.

In many cases, lung injury appears to be an idiosyncratic event and is not easily predicted by dose, time from drug initiation, duration of exposure, or pharmacologic characteristics of the drug. Often, there is no characteristic clinical presentation or pathognomonic histologic pattern of injury associated with a given drug, although certain histologic patterns of lung injury may occur more frequently than others. Thus, establishment of a diagnosis of lung toxicity is frequently a diagnosis of exclusion (Table 65-1). The idiosyncratic nature of pulmonary toxicity suggests that there are host-specific risk factors that influence the development of injury. The risk factors influencing individual susceptibility may be (1) genetically determined, (2) due to concurrent exposures to other medications or environmental agents, (3) related to the individual's comorbid disease, or likely (4) a function of a combination of these factors.

Genetic predisposition to drug-induced injury is not fully characterized but likely is related to individual variability of drug metabolism and biotransformation.[4] While drug metabolism occurs primarily in the liver, through the action of the cytochrome p450 family of enzymes, the lung has an enormous surface area on which blood-borne substances (therapeutic medications, nutritional supplements, illicit drugs, and/or toxins) actively interact with lung tissue and is an active site of metabolism and biotransformation. Cytochrome p450 enzyme levels in lung tissue are estimated to be 10% to 15% of those in the liver, but the existence of lung-specific cytochrome p450 isoenzymes implies lung-specific metabolism of drugs.[5] Host-specific nucleotide polymorphisms affecting drug metabolism appear to be key mediators of variable drug responses in general, and they may confer increased risk of toxicity in certain individuals.[6,7]

MECHANISMS OF PULMONARY INJURY

Mechanisms of lung injury are broadly categorized as direct cytotoxicity and immune-mediated injury, and may include (1) oxidant injury, (2) immunologic and inflammatory cell-mediated injury (including immune complex–mediated injury), (3) interference

TABLE 65-1 General Principles of Drug-induced Lung Injury

- Clinical presentation is nonspecific
- Injury occurs with variable latency from drug initiation
- Lung injury is often dose-independent
- Pulmonary toxicity may be unrelated to the drug's pharmacologic properties
- Acute, subacute, and chronic reactions may be caused by a drug
- A variety of histopathologic patterns may be induced by a drug
- Diagnosis of drug-induced injury is often made by exclusion
- Resolution of injury may occur with drug discontinuation alone
- Rechallenge with the suspected culprit drug is not recommended

with matrix formation or alveolar repair, (4) abnormal protease/antiprotease balance, and (5) interference with lipid metabolism.[7]

The role of drug-induced oxidant injury is well established for nitrofurantoin, mitomycin C, and bleomycin, and it may be the mechanism of injury of other drugs as well.[7] Biotransformation of these drugs results in generation of reactive oxygen species, including hydrogen peroxide (H_2O_2), the hydroxyl radical (•HO), and the superoxide anion (O_2^{-}•), which promote lipid peroxidation, glutathione depletion, and, consequently, cellular dysfunction or cell death.

Immunologically mediated injury is implicated in lung injury events.[7] Lymphocytic or neutrophilic alveolitis and inflammatory cell interstitial infiltrates are present in many cases of drug-induced lung injury, and the elaboration of chemokines and proteases by these cells may lead to cellular injury. The observation that drug metabolite–protein adducts can act as immunogens, resulting in hypersensitivity reactions or other immunologically mediated tissue injury, likely applies to the lung as well as other organs.[8] Complement-mediated injury has been implicated for drugs causing noncardiogenic pulmonary edema (ARDS), particularly opiates and β-agonists.

The role of disruption of phospholipid metabolism due to cellular sequestration has been well established for amiodarone-mediated lung injury, as discussed below.

■ Impact of Concurrent Exposures

The harmful effect of oxygen administration concurrent with the chemotherapeutic agent bleomycin has been well established. However, high oxygen tension does not substantially increase the risk of toxicity for most nonchemotherapeutic agents. It is plausible that the additive effect of supplemental oxygen in promoting oxidant injury may be more relevant for some individuals than others. Other exogenous factors, such as cigarette smoke, may influence lung injury through induction of cytochrome P450 enzymes.

DIAGNOSTIC APPROACH TO THE PATIENT WITH SUSPECTED DRUG-INDUCED RESPIRATORY DISEASE

Confirmation of drug-induced pulmonary toxicity is a diagnostic challenge because pathognomonic criteria for diagnosis seldom exist. The diagnosis of drug-induced disease can be reasonably established, however, if the following criteria are met: (1) history of drug exposure; (2) clinical signs and symptoms, radiologic findings, and histopathology are consistent with previously reported toxicity; (3) alternate diagnoses are excluded (e.g., infection, systemic disease, malignancy); and (4) findings regress with drug discontinuation and/or treatment. Recrudescence of the lung injury following rechallenge with the culprit drug is further confirmation of drug-induced disease, but rechallenge is generally *not* recommended due to the substantial risk of morbidity or mortality.

Recognition of a patient's risk of drug-induced injury is the first step in the diagnostic process. Drug-induced lung disease occurs with prescribed drugs, over-the-counter drugs, herbal or alternative medicine preparations (many of which contain a mixture of substances, any of which might be implicated as the culprit agent), and recreational drugs. Patients may be reluctant to offer accurate information about their use of alternative medicines or supplements and recreational drug use, and the clinician must skillfully elicit the history.

The challenge of diagnosis is compounded by the fact that the latency from the onset of drug use to development of a toxic reaction can be highly variable. The temporal relationship between the respiratory symptoms and/or pulmonary findings and the use of the culprit drug may not be readily apparent when a history is taken. Certain medications (e.g., amiodarone, nitrofurantoin) can cause acute, subacute, or chronic pulmonary toxicity, further complicating the diagnosis. Additionally, new drugs will continue to come on the market, some of which will inevitably cause lung disorders that have not yet been identified. The potential for medications to cause toxic reactions will be recognized only once the drug has been in use for a sufficient length of time to allow low-frequency events, such as drug-induced toxicity, to occur and be recognized.

In many cases, drug reactions are idiopathic, rather than dose-dependent reactions, and are unrelated to the drug's intended pharmacologic properties. Exceptions to these observations include (1) amiodarone, for which there is an increased risk of toxicity with higher daily maintenance dosages, and (2) heroin, methadone, aspirin, propoxyphene, ethchlorvynol, and colchicine, which cause pulmonary toxicity only in the setting of overdose.

The diagnosis of drug-induced lung toxicity is often difficult to establish because patients with this condition typically come to medical attention with symptoms, radiologic findings, and laboratory data that are nonspecific. The clinical presentation of drug-induced lung disease may be similar to other disorders, including infections, hypersensitivity pneumonitis due to environmental antigens, eosinophilic lung disease, systemic rheumatologic or collagen vascular disease, and idiopathic interstitial pneumonias. High-resolution computed tomography (HRCT) has utility in characterizing lung injury but is rarely specific to a drug and may not confidently predict the histologic pattern of drug-induced injury. Even in cases in which lung tissue is obtained by biopsy, the histopathologic features may not fully distinguish drug-induced disease from the alternative disorders or conditions.

An additional consideration is that the underlying disease for which a drug is given may produce pulmonary findings similar to drug-induced lung disease. For example, rheumatoid arthritis may cause pulmonary infiltrates with similar radiographic appearance and histology to toxic reactions induced by the methotrexate, gold, or penicillamine used to treat the rheumatoid arthritis.

Once the clinician has established that a patient has (1) a recognized, identifiable risk of drug-induced lung toxicity, and (2) history, physical examination, laboratory data, and radiographic findings compatible with known patterns of lung injury, then further cytopathologic or histologic evidence may be warranted to further establish the diagnosis. A multidisciplinary approach to diagnosis is recommended with pulmonologists, radiologists, rheumatologists, cardiologists, and pathologists all playing roles.

The technique of bronchoalveolar lavage (BAL) is particularly useful in the diagnostic evaluation of patients with new-onset interstitial lung disease (ILD) in whom evaluation for infection is essential. Analysis of BAL fluid is most useful when it is used in conjunction with a comprehensive clinical history and HRCT.[9] BAL cytologic analysis and culture can be particularly useful to exclude typical or atypical bacterial, fungal, viral, or parasitic infections in patients with suspected drug-induced lung injury. BAL may be helpful in diagnosing diffuse lung malignancies, such as lymphangitic spread of tumor or diffuse pulmonary lymphoma. Lung injury patterns that can be associated with drug-induced injury such as alveolar hemorrhage, whether bland or vasculitic in origin, may be diagnosed by BAL. A grossly cloudy BAL fluid that settles with gravity is consistent with pulmonary alveolar proteinosis.

The cellular differential of the BAL fluid may help narrow the diagnosis in suspected drug-induced pulmonary disease. The most common BAL cellular profile in drug-induced disease is lymphocytosis; a cell differential of ≥25% lymphocytes should earn drug-induced ILD a place in the differential diagnosis of any presentation of ILD. Recent guidelines for the use of BAL do not recommend routine measurement of lymphocyte subsets on all patients with ILD. However, if a lymphocyte alveolitis is suspected or confirmed, the subset measurement may be justified.[9] The T suppressor (CD8+) lymphocyte subset is commonly reported in drug-induced lung hypersensitivity pneumonitis. T helper (CD4+) predominance in the BAL has been associated with immunomodulatory drug injury, including methotrexate, and sirolimus. Other cellular profiles occur in drug-induced disease, and eosinophils and neutrophils are variably present. A percentage of eosinophils ≥25% is consistent with acute or chronic eosinophilic pneumonia, which may be a result of drug-induced injury.

Lung tissue obtained bronchoscopically or surgically may help characterize the injury pattern and may support the diagnosis of drug-induced injury. Lung biopsy, however, is not essential to establish the diagnosis. It is important to recognize that the histologic patterns seen in drug-induced injury, such as nonspecific interstitial pneumonia (NSIP), organizing pneumonia with or without bronchiolitis obliterans, eosinophilic pneumonia, or granulomatous inflammation, are histologically indistinguishable from other etiologies of these lung injury patterns.

Serum markers, including surfactant proteins (SP-A, SP-D), KL-6, and ADAM8, have been associated with drug-induced injury but have not entered into the diagnostic armamentarium for most routine clinical evaluations.[7] Similarly, drug-specific lymphocyte stimulation testing and lymphocyte migration inhibition testing have been shown to be useful in the diagnosis of drug-induced lung disease by some investigators, but these are not available to most clinical practices.

CLINICAL AND HISTOPATHOLOGIC PATTERNS OF INJURY

The entire respiratory system is susceptible to the adverse effects of drugs, including the upper and lower airway, pleura, lung parenchyma, pulmonary vasculature, muscles of respiration, and the central nervous system governing the control of respiration. Among these compartments, parenchymal injury in the form of ILD is the most frequent cause of morbidity and mortality.

Respiratory disease may occur as the sole consequence of drug toxicity, or it may be one manifestation of a systemic drug-induced syndrome. For example, 5% to 25% of patients with drug rash with eosinophilia and systemic symptoms (DRESS) may have lung involvement, most commonly induced by minocycline but also by aromatic anticonvulsants.[10] Drug-induced systemic lupus erythematosus (SLE), with or without pulmonary involvement, may occur from exposure to β-blockers, amiodarone, angiotensin-converting enzyme (ACE) inhibitors, hydralazine, procainamide, isoniazid, methyldopa, minocycline, and tetracycline, among others. In addition, drugs (phenytoin, hydralazine, propylthiouracil, D-penicillamine, and cocaine, among others) can cause the clinical picture of a pulmonary–renal syndrome, with evidence for pulmonary and renal vasculitis.

Parenchymal injury may manifest in the interstitial, alveolar, and/or vascular compartments. Of the processes affecting the lung parenchyma, interstitial involvement is the most common. The major histopathologic forms of ILD—cellular and fibrotic NSIP, usual interstitial pneumonia (UIP), hypersensitivity pneumonitis, organizing pneumonia (with and without obliterative bronchiolitis), eosinophilic pneumonia, desquamative interstitial pneumonitis, and diffuse alveolar damage—have been reported to occur as adverse effects of drugs. Unfortunately for diagnostic clarity, among the many case reports citing the presence of ILD, many have no tissue confirmation of the precise lung histology, and older case reports were published before the current guidelines for classification of ILDs were established. [11] It is important to recognize that few drugs have been reported to cause a single histopathologic pattern of parenchymal injury, and in the cases of many drugs, several patterns of injury may occur[12] (Table 65-2).

The radiographic and histologic characteristics of NSIP and UIP have been defined in the American Thoracic Society/European Respiratory Society (ATS/ERS) international multidisciplinary consensus statements[11,13] in 2002 and 2013.[27,28] These features are

TABLE 65-2 Histopathologic Findings and Nonchemotherapeutic Drug Associations

Histopathologic Diagnosis	Drug	Histopathologic Diagnosis	Drug
Interstitial infiltrates/ fibrosis (acute, subacute, or chronic)	Amiodarone	Eosinophilic lung disease	ACE inhibitors
	β-adrenergic blockers		Amiodarone
	Carbamazepine		Amphotericin B
	Gold salts		Carbamazepine
	Hydralazine		Cephalosporins
	Interferon-α		Erythromycin
	Methotrexate		Ethambutol
	Nitrofurantoin		Gold salts
	Penicillins		Isoniazid
	Phenytoin		Methotrexate
Organizing pneumonia	Amiodarone		Minocycline
	Amphotericin B		Nitrofurantoin
	Carbamazepine		NSAIDs
	Cephalosporins		PAS
	Cocaine		D-Penicillamine
	Gold salts		Sulfonamides
	Interferon-α		Tetracycline
	Minocycline		Trazodone
	Nitrofurantoin		
	D-penicillamine		
	Phenytoin		
	Rituximab		
	Sotalol		
	Sulfasalazine/mesalamine		

TABLE 65-2 Histopathologic Findings and Nonchemotherapeutic Drug Associations *(Continued)*

Histopathologic Diagnosis	Drug
Hypersensitivity pneumonitis	Atorvastatin
	Bupropion
	Carbamazepine
	Cephalosporins
	Ciprofloxacin
	Interferon-α
	Methotrexate
	Nitrofurantoin
	NSAIDs
	Penicillin
	Phenytoin
	Rituximab
	Sertraline
	Sirolimus
	Sulfonamides
Granulomatous inflammation	BCG
	Etanercept
	Infliximab
	Interferon-α
	Methotrexate
	Nitrofurantoin
	Sulfasalazine
Systemic lupus erythematosus	ACE inhibitors
	Amiodarone
	β-adrenergic blockers
	Etanercept
	Isoniazid
	Methyldopa
	Minocycline
	Procainamide
	Tetracycline
Airways disease	Aspirin
	ACE inhibitors
	Adenosine
	β-adrenergic blockers
	NSAIDs
ARDS	Amiodarone
	Gold salts
	HCTZ
	Infliximab
	Methotrexate
	Nitrofurantoin
	Prostacyclins

	Opiates
	Sedative/hypnotics

ACE, angiotensin-converting enzyme; ARDS, acute respiratory distress syndrome; BCG, Bacillus Calmette-Guérin; DAU, diffuse alveolar hemorrhage; HCTZ, hydrochlorothiazide; LTRA, leukotriene receptor antagonist; NSAID, nonsteroidal anti-inflammatory drug; PAS, para-aminosalicylic acid.

effectively indistinguishable whether due to drug-induced, systemic, or idiopathic disease, and thus it is the clinical scenario that is critical to establishing the diagnosis of drug-induced injury. Older literature on drug-induced lung disease does not necessarily conform to recent consensus definitions of NSIP, UIP, or unclassified interstitial pneumonias, making older case series more difficult to interpret. Culprit drugs leading to these interstitial pneumonias include antimicrobials, antirheumatics, tumor necrosis factor (TNF) antagonists, β-adrenergic antagonists, antiarrhythmics, anti-inflammatory drugs, antipyretics, and immunosuppressants.

■ Organizing Pneumonia

Organizing pneumonia (OP) with or without histopathologic evidence of obliterative bronchiolitis is a frequently reported pulmonary injury pattern.[12] The histologic pattern seen in drug-induced parenchymal injury is indistinguishable from cryptogenic organizing pneumonia (COP) and consists of plugs of proliferating fibroblasts, or granulation tissue that fills distal respiratory bronchioles, alveolar ducts, and alveolar spaces. This may be accompanied by mild interstitial inflammation with preserved architecture. Radiographic findings of OP are typically bilateral, patchy areas of consolidation that are often subpleural, with a tendency to lower lobe predominance or distribution along the bronchovascular bundle.

Many of the drugs that have been reported to cause OP are commonly used medications, but the frequency of lung injury among users is low. Among the implicated antimicrobials are cephalosporins, minocycline, nitrofurantoin, amphotericin B, and interferons.[12]

One of the most utilized antiarrhythmic agents, amiodarone, is known to cause OP, as are the anticonvulsants carbamazepine and phenytoin, and the anti-inflammatory agents gold, penicillamine, and sulfasalazine. In patients treated for rheumatoid arthritis (RA) with gold or penicillamine, it is important to distinguish between drug-induced OP and infiltrates reflecting OP due to the underlying RA itself.

The clinical presentation of drug-associated OP is similar to that of idiopathic or cryptogenic OP. Symptoms are nonspecific and may include shortness of breath, nonproductive cough, and, in some cases, low-grade fever and/or pleuritic chest pain. The chest radiograph typically shows bilateral patchy infiltrates that may be migratory over serial radiographs, with interval normal chest radiographs despite continuous drug exposure. As with other interstitial lung disease, the utility of BAL is primarily to exclude an infectious etiology of the infiltrates. There is no specific BAL cellular profile characteristic of OP. Lung biopsy reveals characteristic histopathology, identical to that of COP. Patients with drug-induced OP may have spontaneous resolution of disease when the offending drug is discontinued, but oral corticosteroids may be used to accelerate disease resolution if the patient is symptomatic.

■ Eosinophilic Pneumonitis

Drug-induced eosinophilic lung disease may mimic other eosinophilic pulmonary syndromes, including simple eosinophilic pneumonitis (Loeffler syndrome), chronic eosinophilic pneumonia, acute eosinophilic pneumonia, pulmonary infiltrates with peripheral eosinophilia (PIE), and eosinophilic granulomatosis with polyangiitis (previously known as Churg–Strauss Syndrome). The differential diagnosis of eosinophilic lung disease includes drug-induced injury, and a search for the culprit drug is an integral part of the diagnostic evaluation. Although the clinical presentation of drug-induced eosinophilic pneumonia may be identical to idiopathic conditions, several distinctions can be made. In idiopathic eosinophilic pneumonia, symptoms affect the lung exclusively, while in drug-induced eosinophilic pneumonia, respiratory symptoms may be accompanied by systemic symptoms such as rash and fever. Marked peripheral blood eosinophilia (>1000 cells/mL) suggests drug-induced pneumonitis, rather than acute idiopathic eosinophilic pneumonia, in which the eosinophil count tends to be more modestly elevated or normal.

The diagnosis of drug-induced eosinophilic pneumonia is supported by peripheral blood and/or pulmonary eosinophilia in a setting of exposure to a suspect drug. The diagnosis may be established when other eosinophilic lung diseases are excluded. When evaluating a patient with pulmonary eosinophilia, it is particularly important to exclude infectious causes of eosinophilia to avoid promoting progressive infection and/or death by use of corticosteroid treatment for presumptive drug-induced eosinophilic pneumonia. Tropical pulmonary eosinophilia caused by filarial infection should be suspected if the patient has a consistent travel history. *Schistosoma* and *Paragonimus westermani* are other potential pathogens to be excluded. *Strongyloides*, *Ascaris*, and *Toxocara* are indigenous to the United States and are known to cause pulmonary infiltrates and peripheral blood eosinophilia. Missing the diagnosis of a fungal infection also can be lethal. *Aspergillus* is a ubiquitous fungus that can be difficult to diagnose as a pulmonary pathogen. BAL eosinophilia may be present without definitive evidence of invasive fungal infection, which may require a tissue biopsy for diagnosis. *Coccidioides immitis* is endemic in the southwestern United States, and infection can result in peripheral blood eosinophilia and pulmonary infiltrates. Serologic testing for antibodies to *Coccidioides* and sputum or BAL cultures are useful studies to exclude coccidioidomycosis.

In a review of 196 cases of eosinophilic pneumonia, the most frequently reported drugs associated with eosinophilic pneumonias were daptomycin (n = 32), mesalamine (n = 32), minocycline (n = 17), sulfasalazine (n = 14), nitrofurantoin (n = 12), amitriptyline (n = 4), and amiodarone (n = 4). There were twice as many cases of acute eosinophilic pneumonia (n = 132) as there were cases of chronic eosinophilic pneumonia (n = 61).[14]

Successful management of drug-induced eosinophilic lung disease is achieved by identification and discontinuation of the inciting drug. Typically, resolution of symptoms in drug-induced eosinophilic lung disease occurs with discontinuation of the culprit drug, frequently without the need for corticosteroids. In contrast, idiopathic chronic eosinophilic pneumonia may require months of treatment with corticosteroids, and relapse may occur as steroids are tapered. Relapse of the disease as steroids are tapered is rare in drug-induced eosinophilic disease; recrudescence of the lung infiltrates suggests an alternate diagnosis.

■ Hypersensitivity Pneumonitis

Most cases of pulmonary hypersensitivity occur without accompanying systemic symptoms. The clinical presentation of drug-related pulmonary hypersensitivity typically consists of acute onset of dyspnea, cough, and fever. The radiographic pattern is one of diffuse reticular or peripheral alveolar infiltrates, sometimes accompanied by pleural effusion. The histopathology may include nonnecrotizing granulomas, chronic bronchiolitis, and chronic interstitial inflammation with or without fibrosis. In most cases, drug discontinuation results in disease resolution. A minority of individuals (10%) have persistent radiographic abnormalities after several months, and rarely, progressive disease may occur despite drug withdrawal. In these cases, a trial of corticosteroids is reasonable if the diagnosis has been well established.

Systemic hypersensitivity syndromes with granulomatous inflammation of the lung may be caused by various drugs, most commonly minocycline and the aromatic anticonvulsants phenytoin and carbamazepine, as well as nonsteroidal anti-inflammatory drugs (NSAIDs), and sulfonamides. DRESS can be accompanied by pulmonary histopathology consistent with OP, ILD, or granulomatous inflammation.

■ Noncardiogenic Pulmonary Edema and Acute Respiratory Distress Syndrome

Alveolar disease occurs in the form of noncardiogenic pulmonary edema, diffuse alveolar damage (DAD), and/or acute respiratory distress syndrome (ARDS). It is estimated that approximately 10% of cases of ARDS can be ascribed to drug injury.[12]

Noncardiogenic pulmonary edema may be precipitated by numerous drugs, including aspirin, opiates, calcium channel blockers, some diuretics (e.g., hydrochlorothiazide, acetazolamide), intravenous and inhaled pulmonary vasodilators (e.g., epoprostenol, nitric oxide), methotrexate, TNF-α, radiographic contrast media, tocolytics, and oxytocin, among others.[15] The onset of drug-induced pulmonary edema typically occurs in close temporal proximity to ingestion of the culprit drug and does not have a variable latency of onset.

A variety of mechanisms are implicated in the development of pulmonary edema. Increased pulmonary capillary permeability is the likely cause of aspirin-induced, interleukin-2–induced, and ethchlorvynol-induced edema. Volume expansion and sodium retention likely cause the pulmonary edema associated with the use of β2-sympathomimetic tocolytic agents. Opioid-induced edema is mediated by neurogenic reflex and deposition of immunoglobulin and complement in the lung.[30] Although the mechanisms of pulmonary edema may vary, frequently the resolution of symptoms is prompt within days of drug discontinuation.

Pulmonary edema is common in salicylate intoxication, and the risk is correlated with the degree of intoxication. A prevalence of alveolar edema as high as 20% to 30% has been reported for aspirin-intoxicated adults. An increased risk of edema is associated with chronic aspirin ingestion, older age, positive smoking history, neurologic disease, and proteinuria.[31,32]

In cases of drug-induced ARDS, this condition is considered as a clinical syndrome of lung injury, rather than a specific histopathologic pattern of disease. If we examine the more specific histopathology of DAD, many cases of drug-induced injury have been reported to have these histologic characteristics and diffuse ground-glass attenuation on CT imaging of the lung. The more commonly implicated drugs associated with DAD are amiodarone, methotrexate, infliximab, nitrofurantoin, and many chemotherapeutic agents.[12]

■ Diffuse Alveolar Hemorrhage, Vasculitis, and Pulmonary–Renal Syndromes

Drug-induced diffuse alveolar hemorrhage (DAH) is infrequently reported in the literature on drug-induced pulmonary disease. DAH should be suspected in patients with unexplained ground-glass infiltrates or consolidation, accompanied by anemia. Hemoptysis is not required for the diagnosis and may be absent in as many as one-third of patients with DAH. The classification of drug-induced DAH is based on histopathologic findings and includes (1) capillaritis, (2) bland hemorrhage due to drug-induced coagulopathies, and (3) DAD, the histopathologic finding in ARDS. Drug-induced DAD may lead to bland DAH and has been reported for amiodarone, nitrofurantoin, minocycline, methotrexate, gold, cocaine, and chemotherapeutic agents. Pulmonary capillaritis has been described as an adverse effect of many drugs, but strong associations with its development are reported for relatively few drugs. One of the best-characterized toxicities presenting as DAH is that from propylthiouracil.[16,17] The DAH is a manifestation of a systemic vasculitic syndrome characterized by leukocytoclastic vasculitis, glomerulonephritis, and pulmonary capillaritis. Use of propylthiouracil induces antineutrophil cytoplasmic antibodies (ANCAs) in as many as 46% of patients, although only a minority of these develop pulmonary toxicity; pathogenesis may be mediated by antimyeloperoxidase antibodies.[18] Cases of pulmonary or systemic vasculitis also have been reported for diphenylhydantoin, hydralazine, nitrofurantoin, and leukotriene receptor antagonists. In the case of the last group of drugs noted, there has been considerable discussion as to whether the vasculitis is a toxic effect of the leukotriene antagonists or whether withdrawal of oral corticosteroids leads to identification of pre-existing eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome). At least some reported cases of Churg–Strauss syndrome are unrelated to steroid withdrawal and appear to represent a rare complication of leukotriene antagonists.

Bland hemorrhage without capillaritis can occur (1) in the setting of therapeutic and supratherapeutic anticoagulation, (2) with the use of inhibitors of platelet aggregation (e.g., clopidogrel) and platelet glycoprotein IIa/IIIb inhibitor therapy, and (3) as a complication of thrombolysis. Bland DAH related to D-penicillamine, amiodarone, and cocaine is discussed in the sections on individual drugs in later sections.

■ Cough and Angioedema

Cough induced by angiotensin-converting enzyme (ACE) inhibitors is well characterized in several case series, and guidelines exist to guide management.[19,20] The overall reported incidence of cough associated with ACE inhibitors ranges from 1.5% to 20% and may be increased with concomitant use of ranolazine.[21,22] The latency from initiation of use to the onset of cough is variable, ranging from 1 week to 15 months. While some series have reported increased nonspecific bronchial hyperresponsiveness among subjects with cough, others have not. Symptoms typically resolve promptly 1 to 4 weeks after discontinuation of the drug, but occasionally resolution may take as long as 3 months. Less frequent side effects of ACE inhibitors include PIE, SLE, and subacute ILD, but these do not typically appear in conjunction with ACE inhibitor–induced cough. Angiotensin receptor blockers induce cough much less frequently than do ACE inhibitors and can be considered as alternative therapy.[23]

Angioedema due to ACE inhibitors is a potentially life-threatening complication of these medications. Edema more commonly affects the face (57%) and less commonly the floor or roof of mouth and tongue (26%). In 17%, the oropharynx and glottis are involved.[24] Presenting symptoms may range from simple edema of the lips and/or face to respiratory failure requiring ventilatory support. The latency for onset is even wider than that for cough, ranging from 4 weeks to 4 years after onset of ACE inhibitor use. In one series, 70% presented within the first month of treatment.

Numerous case series have reported a higher incidence of angioedema among African Americans, as well as a higher risk of intubation among those affected in this racial group.[25] Angioedema formation is likely due to elevation of circulating bradykinin as a result of ACE inhibitor–induced inhibition of its degradation, leading to vasodilatation and capillary leak. The effect of impaired bradykinin degradation may be compounded in individuals with genetically based deficiency of other bradykinin metabolizing enzymes. Most experts recommend treatment for angioedema with corticosteroids, H1- and H2-blockers, and, in some cases, epinephrine.

■ Bronchospasm and Anaphylaxis

Drug-induced bronchospasm is a relatively common side effect of many categories of medications, most commonly NSAIDs, antibiotics, and beta blockers.

Bronchospasm triggered by drugs is more common in subjects with underlying asthma, atopy, or bronchial hyperreactivity. These reactions are more common in women than in men, and there appears to be familial predisposition to reactions to some drugs.[26] Symptoms range from mild chest tightness and dyspnea on exertion to respiratory failure in susceptible individuals. Aspirin and NSAIDs are commonly implicated in bronchospasm, in one series accounting for as many as 24% of bronchoconstrictive reactions, ranging from mild to severe.[27] Other agents more commonly implicated in bronchospasm and anaphylaxis include sulfonamides, omalizumab, halothane, heparins, protamine, insulin, and neuromuscular blocking agents.

Anaphylaxis is mediated by a variety of mechanistic pathways including (1) IgE-mediated anaphylaxis, (2) non–IgE-mediated anaphylactoid reactions, (3) alteration in the cyclooxygenase (COX) and lipoxygenase pathways, and (4) mast cell activating disorders.[28,29] The effects of some drugs can be mediated by multiple mechanisms—for example, antibiotics, biologics, NSAIDs, and vaccines can lead to anaphylaxis via IgE mediated allergic reactions, but aspirin and NSAIDs will also exert their effects through non-IgE leukotriene-mediated mechanisms. In the United States, antimicrobials have been implicated as the cause of 0.7% to 10% of cases of severe bronchospasm, and penicillin remains the most important cause of anaphylaxis, accounting for up to 75% of cases annually.[30]

■ Constrictive Bronchiolitis

Constrictive bronchiolitis causes adverse lung reaction relatively infrequently. Agents that have been reported to cause small airway inflammation (bronchiolitis) include medications used in the treatment of RA, such as D-penicillamine and gold salts.[12] Interpretation of earlier literature on D-penicillamine and gold-induced bronchiolitis is complicated by the fact that RA itself can cause bronchiolitis.[31] Use of these agents has been largely supplanted by disease-modifying antirheumatic drugs, immunosuppressants, and biologics, but these implicated agents may still be used in certain cases. Drug-induced bronchiolitis typically causes shortness of breath, with or without wheezing, and cough. Spirometry may not detect small airway disease until obstruction is severe, but high-resolution CT imaging protocols may show centrilobular nodules and/or tree-in-bud opacities, as well as mosaic attenuation of the lung parenchyma, reflective of air trapping.[32]

■ Pulmonary Hypertension

Pulmonary hypertension is a relatively infrequent complication of drug therapy, but because of the subtlety of the onset of disease, paucity of symptoms until significant vascular compromise has occurred, and potential for eventual vascular collapse and death, it is critical to recognize drug-induced pulmonary hypertension early in its course. Among the drugs known to cause pulmonary hypertension are dasatinib, amphetamines, methamphetamines, cocaine, anorexigens, and toxic contaminants of food and nutritional supplements (e.g., rapeseed oil and tryptophan).[33]

The association of appetite suppressants with pulmonary hypertension dates to the late 1970s when reports of unexplained "primary" pulmonary hypertension were first published. The "epidemic" of pulmonary hypertension was linked to the use of aminorex fumarate, an amphetamine-derived appetite suppressant that came into use because its potential for addiction and abuse was lower than that of amphetamine. The use of aminorex was associated with a significant rise in the incidence of pulmonary hypertension, primarily among women in Germany, Austria, and Switzerland. Development of disease occurred as early as weeks to months from the onset of use of the drug, with a dose-dependent risk as high as 2 in 100. The mechanism of action on the pulmonary vasculature is through the release of catecholamines, including dopamine. The epidemic subsided as use of the drug declined.

Another amphetamine derivative, fenfluramine, was introduced as an appetite suppressant in the European market in the 1960s and the U.S Market in the 1970s. It was withdrawn from the U.S market in 1997 due to the association with excess rates of pulmonary hypertension and valvular heart disease, but remains relevant today because these adverse effects can be long lasting. The mechanism by which anorexigen drugs cause pulmonary hypertension is likely by acting as indirect serotonin (5-HT) receptor antagonists, inhibiting 5-HT reuptake and causing release of 5-HT from platelets. 5-HT in turn mediates vasoconstrictive responses in the pulmonary vasculature, and stimulation of 5-HT transporter expression leads to hyperplasia of pulmonary artery smooth muscle cells.[33]

Two landmark reports supported a causal relationship between pulmonary hypertension and the use of fenfluramine and dexfenfluramine. The first was published in 1993, describing a cohort of young to middle-aged users of the anorexigens who developed pulmonary hypertension indistinguishable from idiopathic primary arterial pulmonary hypertension.[34] This was followed in 1996 by the findings of the International Primary Pulmonary Hypertension Study Group, which published a case-control series of 95 patients with pulmonary arterial hypertension.[35] An odds ratio (OR) of 23.1 for development of disease was found among those who had used an anorexigen for more than 3 months, with an estimated incidence of 1 to 2 cases per million users per year. Fenfluramine was withdrawn from the market in 1995 due to its association with increased risk for pulmonary hypertension, as well as its role in the development of valvular heart disease in users of the fenfluramine–phentermine combination anorexigen known as "fen-phen."[36]

Epidemics of pulmonary hypertension also have been reported due to contaminants in a specific manufacturer's rapeseed oil in Spain, and from use of an over-the-counter L-tryptophan preparation that resulted in the eosinophilic myalgia syndrome, characterized by a systemic syndrome that included acute lung injury and pulmonary hypertension.

The use interferon-α and interferon-β in the treatment of hepatitis C and multiple sclerosis has been associated with the development of pulmonary hypertension likely through the release of endothelin 1.[37,38]

TOXICITY ASSOCIATED WITH SELECTED DRUGS

The following drugs have been selected for discussion because (1) they are very commonly used, (2) have important forms of toxicity associated with their use, or (3) have more recently entered into our pharmacologic armamentarium and, therefore, are likely associated a lower level of awareness of their potential toxicity to the respiratory system.

■ Cardiovascular Drugs

Below we consider cardiovascular drugs that are well recognized to be associated with pulmonary toxicity.

Amiodarone

Adverse reactions to amiodarone have been reported in a variety of tissues, including the lung, liver (liver function abnormalities and increased tissue attenuation on radiographic imaging), thyroid (thyrotoxicosis), skin (discoloration), and cornea.

Amiodarone is an iodinated, benzofuran-derivative antiarrhythmic used for management of life-threatening supraventricular and ventricular arrhythmias. Both amiodarone and its major metabolite, N-desethylamiodarone, are cationic, amphiphilic compounds with high lipid solubility, causing the drug to accumulate in tissues with high lipid content including adipose tissue, thyroid, liver, and lungs. The elimination half-life of amiodarone is 30 to 100 days, and the drug has been found in lung tissue as long as 1 year after discontinuation of therapy. These pharmacokinetic characteristics contribute to the drug's potential toxicity and impact treatment strategies since the toxic effects of the drug can persist even after discontinuation.

One of amiodarone's biochemical effects is to impair normal phospholipid catabolism by phospholipases, thereby leading to cellular phospholipidosis. The accumulation of phospholipids in the cell may cause direct cellular injury, and evidence supports cellular injury through production of the unstable aryl radical as amiodarone is deiodinated, leading to reactive oxygen species formation and cell death. Direct cellular injury affects type 2 pneumocytes, endothelial cells, and fibroblasts, and immune-mediated hypersensitivity further contributes to the lung tissue injury.[39] The impairment of phospholipid metabolism results in the lamellar inclusions and lipid-laden foamy macrophages that characterize the histology seen on lung biopsy and BAL. These findings are characteristic of amiodarone exposure and are not indicative of toxicity unless accompanied by the lung injury patterns discussed below.

The first reports of amiodarone pulmonary toxicity were published in 1980 and were followed by larger series of patients as amiodarone was tested in the United States in the early-to-middle 1980s. Based on two studies published in 1987, the clinical picture of amiodarone pulmonary toxicity emerged as a syndrome of pulmonary infiltrates and respiratory symptoms, most often cough and dyspnea of subacute or chronic onset, accompanied by fever, malaise, and chest discomfort in 50% of those affected. In one series, 11 of 171 patients (6.4%) treated with 400 to 1200 mg of amiodarone developed pulmonary disease; in another series, 15 of 154 subjects (9.7%) developed disease.[40–42] The time from initiation of therapy to development of symptoms was 61 to 465 days in one series and 30 to 720 days in the other. Subsequent reports have supported these initial observations.

Disease Prevalence and Risk Factors for Amiodarone Toxicity Amiodarone toxicity is estimated to occur in 10% of patients who have used the medication for 1 year, and the cumulative prevalence may be as high as 5% to 10% over years of drug use.[12] Predisposing risk factors for the identification of amiodarone pulmonary toxicity include older age, duration of therapy for >6 months, higher daily dosages, male gender, renal disease, and pre-existing lung disease.[43] The risk of pulmonary toxicity roughly correlates with daily dose, and most reports of amiodarone toxicity have been of patients receiving doses greater than 400 mg daily. In one series, 0.1% to 0.5% of patients on 200 mg per day developed amiodarone pulmonary toxicity, while as many as 50% of those using the highest dosages (e.g., 1200 mg per day) were affected.[44] The lower doses of amiodarone that are more commonly used are considered to be safer than higher doses; however, toxicity has been reported at doses as low as 200 mg per day.

Pre-existing lung disease may enhance the risk of toxicity. It is not entirely clear whether there is higher incidence of toxicity in those with pre-existing lung disease, or if prior disease results in earlier perception of symptoms and scrutiny for pulmonary causes of dyspnea. The AFFIRM (Atrial Fibrillation Follow-up of Rhythm Management) trial reported a higher risk of diagnosis of amiodarone lung toxicity if the patient had pre-existing pulmonary disease; however, there was no higher risk of either pulmonary death or all-cause mortality.[45] Patients with atrial fibrillation treated with amiodarone in the setting of chronic obstructive pulmonary disease (COPD) had a hazard ratio of 2.53 (2.2–2.89) compared to those without COPD.[43] It is considered acceptable to use amiodarone in the setting of pre-existing lung disease if vigilance is maintained for the development of symptoms suggestive of amiodarone toxicity.

The North American Society of Pacing and Electrophysiology has offered general guidelines for management and monitoring of patients on amiodarone, acknowledging that the long half-life (~100 days) makes organ toxicity potentially more severe and difficult to reverse. The Society recommends follow-up every 3 months for the first year of use, and subsequently every 6 months. Baseline pulmonary function testing is recommended for those with underlying lung disease along with careful follow-up, but baseline testing may be omitted if the patient has no known lung disease and no chronic respiratory complaints.[46]

Amiodarone is frequently used in the setting of thoracotomy perioperatively to prevent and treat atrial fibrillation. Earlier literature reported a retrospective analysis of 552 patients undergoing lung resection or pneumonectomy in which there appeared to be an 11% rate of acute lung injury ARDS among patients treated with amiodarone compared with 1.8% among those who were not treated with the drug.[47] Several authors have suggested that amiodarone pulmonary toxicity may be triggered by administration of high concentrations of supplemental oxygen, or that oxygen may act in synergy with amiodarone to enhance cellular injury. However, confounding variables have not always been well characterized in the reported cases of possible acute lung toxicity, and a more recent large meta-analysis (1075 patients, 5 randomized controlled studies) did not find a significant incidence of acute amiodarone pulmonary toxicity in the perioperative thoracic surgery setting.[48] The Society of Thoracic Surgeons practice guidelines for management of atrial fibrillation in the setting of thoracic surgery recommend caution in using amiodarone in patients undergoing pneumonectomy, but grade the evidence for this recommendation only as level C.[49]

Clinical means of decreasing the risk of amiodarone toxicity have not been well characterized. Dronedarone hydrochloride, an amiodarone-like antiarrhythmic, was developed to decrease the risk of pulmonary toxicity by the addition of a methyl sulfonyl group. However, several cases of dronedarone pulmonary toxicity are reported, with the earliest onset 2 weeks after initiation of dronedarone with ground-glass opacities and consolidation suggestive of OP, and other cases occurred at 1 month after drug initiation with ground-glass opacities on imaging and DAD on biopsy, and diffuse interstitial infiltrates with a subpleural predominance and fibroblastic foci histologically.[50,51] In some case reports the subjects had been on amiodarone immediately prior to initiation of dronedarone, and implication of the latter drug is less confident. A protective effect of ACE inhibitors against amiodarone pulmonary toxicity is supported in several publications.[52,53]

Clinical Presentation of Amiodarone Toxicity The typical clinical presentation of amiodarone pulmonary toxicity is a nonproductive cough and dyspnea, sometimes accompanied by pleuritic chest pain, fever, malaise, and/or weight loss. Symptom onset is most often 6 to 24 months into treatment (100 to 150 g cumulative dose) but can range from a few days to 10 years into therapy. Most subjects have an insidious onset of symptoms over several months, but fatal amiodarone-induced pulmonary toxicity occurring 2 weeks into therapy has been reported.[39]

The earliest abnormality identifiable on pulmonary function testing of affected individuals is impairment in diffusing capacity for carbon monoxide (DL_{CO}). There may be an accelerated decline in the DL_{CO} as the disease progresses, accompanied by mild restrictive physiology. Since a low DL_{CO} is not specific for amiodarone toxicity, a decline should not necessarily prompt discontinuation of the drug but should trigger evaluation for other cause(s) of the impairment.

Radiographic and Histologic Findings of Amiodarone Toxicity The radiographic and histologic findings associated with amiodarone pulmonary toxicity are not stereotypic and may include acute, subacute, and chronic interstitial pneumonia, OP, DAD, pulmonary fibrosis, single or multiple nodules, eosinophilic pneumonia, or diffuse alveolar hemorrhage.[12] Typical radiographic findings in patients with subacute or chronic onset of disease are diffuse or patchy, interstitial or mixed alveolar–interstitial infiltrates, which are either bilateral or unilateral (Fig. 65-1). Mild cases of toxicity may be characterized by a diffuse ground-glass pattern on HRCT, often in a peripheral, subpleural distribution. Focal and patchy areas of higher attenuation may be superimposed on the ground-glass opacification. Alveolar opacities may correspond to areas of OP that are indistinguishable from idiopathic OP. Amiodarone toxicity should be considered in cases of migratory infiltrates that are consistent with OP but that are poorly responsive to steroids. Amiodarone-induced fibrosis occurs in 5% to 7% of patients diagnosed with amiodarone pneumonitis and may be present at disease presentation. Honeycombing is rare. The most common histology observed is subacute or chronic ILD, often consistent with nonspecific interstitial pneumonia. There are also many reports of OP, pulmonary fibrosis, and DAD/ARDS, and

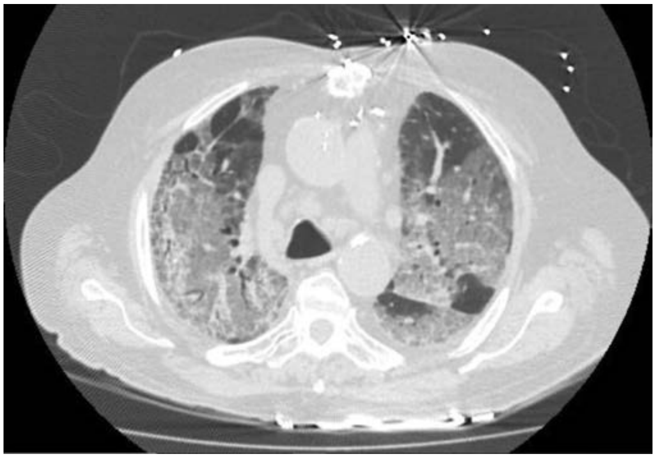

Figure 65-1 Amiodarone lung toxicity. ARDS superimposed on mild underlying fibrosis at 3 months after initiation of amiodarone in an 80-year-old man with progressive dyspnea. Dyspnea began insidiously approximately 1 month after amiodarone load.

fewer reports of solitary or multiple nodules (which can be fluorodeoxyglucose [FDG]-avid on PET imaging). Eosinophilic pneumonia and diffuse alveolar hemorrhage are more rare.[12]

Laboratory Analysis in Amiodarone Toxicity Laboratory analyses have little utility in the diagnosis of amiodarone-associated lung toxicity. Common laboratory abnormalities are nonspecific and include mild leukocytosis and elevation in serum lactate dehydrogenase (LDH). Earlier trials of amiodarone identified elevated sedimentation rates (range of 39–150 mm/h) in 9 of 11 patients with pulmonary toxicity, but nonspecificity of the ESR makes this test less useful in the clinical setting.[40] Identification of brain natriuretic peptide (BNP) that is normal, or at a patient's baseline, may be useful in distinguishing pulmonary causes of dyspnea from congestive heart failure.

Diagnostic Evaluation and Management of Amiodarone Toxicity The challenge to the practitioner considering the diagnosis of amiodarone pulmonary toxicity is that the differential diagnosis is broad for dyspnea with pulmonary infiltrates in patients with known cardiac disease. Cardiogenic and noncardiogenic etiologies must be excluded. Consideration must be given to cardiac conditions, including ischemic and nonischemic cardiomyopathies, diastolic dysfunction, mitral valve disease, aortic stenosis, and atrial fibrillation. Noncardiogenic causes may include infections; the broad range of idiopathic interstitial pneumonias; malignant causes of infiltrates (e.g., lymphangitic spread of tumor or lymphoma); systemic diseases such as sarcoidosis, amyloidosis, or autoimmune disease; exposures to inhaled agents (e.g., occupational inorganic dust exposures, or organic inhalations, with subsequent development of hypersensitivity pneumonitis); and exposures to drugs apart from amiodarone.

The risks of invasive workup must be weighed against those of empiric therapy, which includes drug discontinuation and, possibly, corticosteroids. BAL may reveal a lymphocytosis, often with a predominance of CD8+ lymphocytes, reflective of a lymphocytic alveolitis. This finding, however, is not consistently reported, and some affected individuals may have elevated BAL neutrophils as well. Significant BAL eosinophilia is rare. Abundant alveolar macrophages with a "foamy" cytoplasm, indicative of undigested phospholipids, are found in all subjects chronically exposed to amiodarone and are not indicative of pulmonary toxicity per se. Hemosiderin-laden macrophages are infrequently found, since alveolar hemorrhage is rare. As the BAL findings are neither sensitive nor specific for amiodarone pulmonary toxicity, the role of BAL in the diagnosis is to exclude other causes of the clinical picture, especially infection.

Lung biopsy findings, however, may support the diagnosis of amiodarone toxicity. Earlier reports of amiodarone pulmonary toxicity describe DAD of variable severity in all affected subjects. Those more severely affected had evidence of acute DAD, with abundant hyaline membranes and reactive type II pneumonocytes lining the alveoli, while others showed organizing DAD with interstitial and intra-alveolar proliferation of fibroblasts and prominent type II pneumocytes. All cases had abundant "foamy" macrophages in the alveolar spaces. The foamy appearance of the cytoplasm is due to the presence of lamellar bodies (~1 μm in diameter) containing lipid particles, reflecting the disrupted lipid metabolism caused by amiodarone.

The diagnosis of amiodarone pulmonary toxicity is supported by the presence of lamellar bodies in macrophages, pneumocytes, bronchiolar epithelium, and/or endothelial cells, but the diagnosis is more confidently made if there are interstitial lymphocytic infiltrates and diffuse lymphoid hyperplasia, and in some cases follicular bronchiolitis, eosinophilic infiltrate or poorly formed granulomas.[54] Despite the early reports, few patients with amiodarone pulmonary toxicity have DAD pathologically unless they fit the clinical picture of ARDS. Alveolar hemorrhage may be present, but it is not a common feature of amiodarone toxicity.

In contrast to other types of drug-induced pulmonary toxicity, resolution of amiodarone-induced toxicity often does not occur with discontinuation of the drug alone. Amiodarone becomes sequestered in tissues, and the clearance of drug is typically prolonged. Depending on the severity of respiratory symptoms, practitioners often may need to treat affected patients with corticosteroids. Specific dosages of prednisone have not been studied for efficacy, but 0.5 to 1 mg/kg is a reasonable starting point in most cases. Due to the pharmacokinetic characteristics of amiodarone, the required duration of therapy may be several months, and recrudescent disease after tapering of corticosteroids is not uncommon.

β-Adrenergic Receptor Blockers

The most common adverse effect of β-adrenergic blockers on the respiratory system is precipitation of bronchospasm in asthmatics and patients with reactive airway disease. The high frequency of clinically significant bronchospasm in hypertensive asthmatics treated with nonselective β-adrenergic blockers, such as propranolol, requires that these agents be avoided in asthmatics. β1-Receptor–selective agents and the α- and β-receptor blocker labetalol are better tolerated but should be used with considerable caution in asthmatics. The use of β-adrenergic blockers is not contraindicated in patients with COPD. Many individuals with COPD tolerate β-adrenergic blockers without significant decrement in their lung function. Patients with COPD who have clinical or spirometric evidence of airflow obstruction responsive to bronchodilators should be observed carefully for bronchospasm upon initiation of these agents. Overall, the cardiac benefit of β-blockade in these subjects likely outweighs any risk.

Pulmonary parenchymal injury associated with the use of β-adrenergic blockers is not common, but it warrants mention because of the ubiquitous use of these agents. Subacute interstitial infiltrates, PIE, and pulmonary edema have been reported in conjunction with the use of acebutolol, propranolol, labetalol, nadolol, and pindolol. Thus, the clinician should be vigilant for these reactions from using β-adrenergic blockers as a class. SLE has been reported with the use of acebutolol, propranolol, labetalol, and pindolol.

Hydralazine

Hydralazine-induced pulmonary disease is not common, but it can be associated with systemic autoimmune disease that is potentially fatal even when recognized.[55,56] Half of the patients on daily doses of greater than 200 mg have a positive ANA, but only 10% of these patients develop clinical symptoms. The most important reported complication of long-term use of hydralazine is drug-induced SLE, which occurs more frequently if daily dosing is greater than 200 mg or the cumulative dose exceeds 100 g. In addition, there have been cases of pulmonary–renal syndrome associated with the use of hydralazine.[55,57,58] Pleuropulmonary manifestations occur in 30% of affected subjects, and isolated pulmonary parenchymal disease is rare. Subacute ILD/NSIP, OP, and DAH also have been documented.

Hydrochlorothiazide

The most commonly reported pulmonary side effect of the diuretic hydrochlorothiazide (HCTZ) is noncardiogenic pulmonary edema or ARDS.[59] Pulmonary edema was first reported in 1968 as a potentially life-threatening complication of HCTZ use. The onset of symptoms is typically acute and less often occurs later in the course of HCTZ use. Typical symptoms and signs include acute dyspnea and hypoxemia; fever, tachycardia, hypotension, and shock may accompany the dyspnea. Immunologically mediated capillary leak has been suggested as a possible mechanism of action. IgG deposition in the alveolar membrane and elevated serum IgM have been reported.

Management is supportive, and symptom resolution typically occurs in a few days. Rechallenge with HCTZ can cause recrudescent pulmonary edema and is not recommended. Since HCTZ is a widely used diuretic, frequently used in patients with cardiovascular disease who are prone to pulmonary edema, the true incidence of drug-induced noncardiogenic pulmonary edema may be underreported.

Statins

In light of the wide use of statins (3-hydroxy-3-methylglutaryl coenzyme A [HMG-CoA] reductase inhibitors), there have been a number of investigations into their potential to cause lung injury. Clinicians are more familiar with the well-reported myositis and hepatotoxicity associated with statins than they are with pulmonary side effects. Lung injury has been reported in conjunction with the use of various statin compounds and may be a class effect, but the data are conflicting. A study published in 2008 pulled events from the U.S. Food and Drug Administration adverse event reporting database (FDA-AER) through 2007 and reviewed case reports in the literature. In all, 162 events were reported as statin-induced ILD, and the authors estimated that for every 10,000 adverse events associated with statins between 1 and 40 events could be ILD.[60] The prevalence of interstitial lung abnormalities (ILA) was examined in 2207 subjects in the COPDGene cohort, and it was noted that statin use was associated with the presence of interstitial abnormalities of CT imaging: of the patients with ILA, 38% were on statins and 27% of patients without ILA were using statins.[61] While these studies generated interest, neither proved causality.

The case reports in the literature suggest that the latency and radiographic and histopathologic pleuropulmonary manifestations associated with statins are variable. The reported latency of onset ranged from 1 week to 120 months (mean, 34 months; SD, ± 35 months), and the most common presenting complaints were nonspecific: dyspnea, cough, and fever. The radiographic findings may include ground glass and alveolar opacities that are diffuse in distribution, sometimes with patchy consolidation, interstitial infiltrates or fibrosis; pleural effusion is reported, but is rare.[62–64] Analysis of BAL fluid shows no characteristic predominant cellular profile. Foamy macrophages suggesting pulmonary phospholipidosis have been observed in some but not all cases. When obtained, biopsies demonstrate histopathology consistent with NSIP or hypersensitivity pneumonitis. Resolution of presumed statin-induced lung disease has been achieved with drug discontinuation, with or without corticosteroid therapy.

A subsequent study has lessened the concern for statin-induced lung injury. A nested case-control analysis of a cohort of 1.4 million patients in the Quebec health administrative database (1990–2005) identified 6665 possible cases of statin-induced ILD and compared them with matched controls.[65] After adjusting for comorbidities and confounders, there was no association found between statin use and incidence of ILD.

■ Anticonvulsants

Various types of pulmonary injury may result from exposure to phenytoin. Among the reported patterns of injury are pulmonary hypersensitivity reactions, which may be a component of systemic hypersensitivity (see the prior discussion of DRESS), or hypersensitivity pneumonitis without systemic manifestations.[66] In some cases, parenchymal infiltrates are accompanied by peripheral blood eosinophilia, suggesting chronic eosinophilic pneumonia.[67] Lymphocytic interstitial pneumonitis and OP have been described as well.[12]

■ Anti-inflammatory and Immunomodulatory Agents

A variety of anti-inflammatory and immunomodulatory agents have been associated with pulmonary toxicity.

Aspirin and Nonsteroidal Anti-inflammatory Drugs

The most common pulmonary adverse reaction associated with aspirin use is bronchospasm, which may occur with therapeutic dosing in aspirin-sensitive individuals. Aspirin and NSAIDs induce bronchoconstriction by diverting arachidonic acid metabolites toward the lipoxygenase metabolic pathway, thereby leading to enhanced leukotriene-mediated airway inflammation and bronchoconstriction. Less commonly reported pulmonary complications of aspirin use include PIE syndrome, DAH, pulmonary hypersensitivity, vasculitis, and ARDS.

Acute salicylate poisoning produces symptoms of central nervous system toxicity (tinnitus, vertigo, nausea, vomiting, and hyperventilation) in mild to moderate overdose, and it may result in coma, severe metabolic acidosis, and noncardiogenic pulmonary edema with critical overdoses. Pulmonary edema occurs in as many as 20% to 30% of patients with severe salicylate poisoning and may result in respiratory failure, often exacerbated by severe metabolic acidosis. Risk factors for salicylate toxicity include increased age and chronic aspirin ingestion. Management of severe toxicity includes supportive intensive care and sodium bicarbonate infusion to promote drug excretion.

NSAIDs are widely used and generally well tolerated. However, NSAIDs may cross-react with aspirin, producing a variety of allergic and pseudoallergic reactions affecting upper and lower airways. NSAIDs cause bronchospasm in susceptible individuals with symptoms ranging from mild to severe. NSAIDs also cause anaphylactic reactions through the same mechanism as that for aspirin. Eosinophilic pneumonia is also reported as an NSAID class effect with most cases in the literature associated with naproxen, but also with fenbufen, ibuprofen, and diclofenac.[14,68] The onset of symptoms is typically acute with in the first days of therapy, and resolution may require corticosteroids if the reaction is severe.[68]

The bleeding tendency induced by NSAIDs is well known, and reports exist of pulmonary hemorrhage associate with their use.

■ Nonbiologic Disease-Modifying Antirheumatic Drugs

The task of determining whether the presence of ILD in the setting of rheumatoid arthritis (RA) is due to new-onset RA-ILD, exacerbation of pre-existing ILD, or induction of ILD due to exposure to nonbiologic or biologic disease-modifying antirheumatic drugs (DMARDs) has made clinical management of pulmonary disease in these patients extremely challenging. A systematic review of a case series between 1975 and 2013 makes note that due to the absence of pathognomonic findings to prove drug-induced ILD, causality often is difficult to ascertain despite a time of symptom onset and clinical features that suggest drug induced-ILD.[69] Case reports and series are useful to characterize the drug-associated lung disease but give us few clues to the actual incidence of disease among users of specific medications. Overall, the incidence of pulmonary toxicity due to nonbiologic and biologic DMARDs is low even among patients with pre-existing lung disease, but the incidence of infections among treated patients is considerable. A recent case series describes a cohort of 1129 patients with RA, 87 (7.7%) of whom had lung involvement. The subjects with lung involvement were followed over a period of 6.7 ± 4.1 years. Only 2 cases of MTX lung toxicity were reported (3.1% of the treated RA-lung disease cohort), and there were no cases of rituximab-associated lung injury among the 26 RA-ILD patients using this medication.[70] Importantly, over the follow-up period, 22 patients (25.3%) developed respiratory infections requiring hospitalization, illustrating the importance of vigilance for infection among patients with RA-associated lung disease.

Methotrexate

Methotrexate (MTX) is the nonbiologic DMARD most frequently appearing in reports, with fewer reports of leflunomide, sulfasalazine, gold, and azathioprine lung toxicity.[69] MTX is a dihydrofolate reductase inhibitor used as an anti-inflammatory and immunosuppressant, as well as a chemotherapeutic agent when used in higher doses. Despite the availability of newer antirheumatic drugs, MTX has retained its position as a first-line DMARD for the management of RA. MTX affects cell replication through inhibition of dihydrofolate reductase, the enzyme that converts folic acid to its active coenzyme, tetrahydrofolate, allowing it to serve as a one-carbon carrier in the synthesis and repair of DNA. The major nonpulmonary side effects of MTX correlate with the degree of folate deficiency and can be mitigated through folate replacement. In contrast, pulmonary toxicity does not correlate with folate deficiency and may be seen at doses as low as 7.5 mg/week, a conventional starting dose for treatment of RA. Conditions that have been identified as risk factors for MTX lung toxicity include diabetes mellitus (OR, 35.6), hypoalbuminemia (OR, 19.5), rheumatoid pleuropulmonary disease (OR, 7.1), chronic kidney disease, previous use of other disease-modifying agents (e.g., gold, sulfasalazine, penicillamine), genetic predisposition (HLA-A31:01), male sex, and older age (OR, 5.1).[71,72]

MTX-induced pulmonary toxicity typically occurs within the first 2 years of treatment, but it can occur as early as 1 month into therapy. Pulmonary symptoms are most often subacute in onset, presenting over days to weeks, and include dyspnea, cough, fever, and less frequently, chest pain (<10%).[73] Symptoms may also develop acutely.[74] Radiographic changes are interstitial and bilateral in the majority of cases with features consistent with NSIP, or a mixed alveolar–interstitial pattern that may appear with ground-glass opacities on CT imaging.[73] Radiographic features less commonly appear as nodular consolidation, suggesting OP or a bronchiole-centric (tree-in-bud) pattern.[72] Fibrotic changes are less common. Laboratory testing is nonspecific, but a mild peripheral blood eosinophilia may occur in 20% to 40% of patients with subacute pulmonary toxicity.[72]

Diagnosis is challenging in with RA and suspected MTX-induced pulmonary toxicity, because similar clinical presentations may occur as a manifestation of RA itself. The most important diagnosis to exclude is infectious pneumonia, including that from opportunistic organisms. A diagnosis of MTX-induced lung disease is suggested by a predominance of lymphocytes, rather than neutrophils, on BAL.[75,76] The lymphocytic BAL fluid of MTX-induced hypersensitivity pneumonitis often has a CD8-predominant profile (low CD4:CD8 ratio), but not exclusively so. It appears that the type of inflammatory cells may predict disease severity and acuity. In one study of 56 cases of MTX pulmonary toxicity, a lymphocyte-predominant BAL fluid was associated with late onset of symptoms (>6 months from drug initiation) and lower mortality than in those with neutrophil-predominant BAL.[77] Histopathology is varied and may demonstrate ill-formed granulomas suggestive of hypersensitivity pneumonitis, NSIP, OP, or DAD in cases of acute toxicity.[72] PIE syndrome also has been reported.[99]

As with other pulmonary toxicities, prompt drug withdrawal is critical; resolution of lung injury follows in most patients. Overall fatalities have been reported in earlier series to be as high as 17%, and it appears that acute and subacute onset is associated with higher mortality.[77] Corticosteroids may accelerate recovery in those with severe disease or symptoms refractory to drug withdrawal alone. Rechallenge with methotrexate is generally not recommended, but rechallenge has been tolerated in some, arguing against hypersensitivity as the mechanism of injury in certain subjects.

Leflunomide

Use of leflunomide as a DMARD began in the late 1990s. The incidence of leflunomide lung toxicity is not as high as that associated with MTX, but concerns for leflunomide-induced lung injury have been present since its earliest use. If interstitial lung injury occurs in the setting of leflunomide use, it typically occurs within 20 weeks of initiation of the medication, and in those with underlying ILD, pneumonitis developed earlier, within 12 weeks of use.[78] Radiographic findings are variable and most commonly include bilateral ground-glass opacities and/or interstitial infiltrates.

Data from a postmarketing analysis were published by Japanese investigators from a large cohort of 5054 patients with RA treated with leflunomide.[79] Based on clinicians' diagnosis, 61 patients (1.2%) developed ILD or had exacerbation of pre-existing ILD, and there were deaths reported within the cohort. The cohort spans a time period before and after the manufacturer imposed a safety notice in leflunomide labeling, suggesting that there was an increased risk of adverse pulmonary effects among patients with pre-existing ILD. The rate of lung adverse events dropped after the warning was issued and fewer patients with pre-existing ILD were treated with leflunomide. The rate of progressive ILD among those without pre-existing ILD was only 0.7% overall compared with an incidence rate of 6% among those with pre-existing ILD (OR, 8.17) before warnings were issued. Additional risk factors for leflunomide lung toxicity identified in this cohort included male sex, age ≥60 years, low body weight (<40 kg), smoking history, and initial use of a loading dose of leflunomide.[79] Similarly a cohort of 1010 patients with RA treated with leflunomide had 10 cases of ILD occurring overall, with a significantly higher incidence among those with pre-existing ILD, emphysema, or tuberculosis.[80] It has been noted with interest that the reported incidence of leflunomide-associated ILD appears to have been higher in Japan and Korean cohorts compared with Western subjects, but the reasons for the disparity are not clear. The prevalence of pre-existing ILD was high in the Japanese cohort (14.7%), and this alone may account for the reported differences.[79] The possibility of genetic predisposition to RA-ILD or leflunomide-induced ILD has been hypothesized but by no means proven. Subsequent analyses have suggested that the apparent risk of leflunomide toxicity is more likely due to channeling bias; the use of the drug is channeled to high risk patients, many of whom had pre-existing RA-ILD or history of MTX use.[81] A recent meta-analysis of double-blind, randomized, controlled studies of adult RA patients treated with leflunomide compared with other DMARDs (predominantly MTX) found no excess risk of lung toxicity associated with the use of leflunomide, nor was there increased risk of infections.[82]

The use of leflunomide is warranted in appropriate patients with vigilance for pulmonary adverse effects, especially among those with pre-existing lung disease.

Sulfasalazine and Mesalamine

Sulfasalazine is used as a DMARD and also is commonly employed in the treatment of inflammatory bowel disease, as is mesalamine (also known as mesalazine). Both agents are 5-aminosalicylates and have similar pulmonary adverse effect profiles. Sulfasalazine and mesalamine are among the drugs that most commonly induce eosinophilic pneumonia.[14,83] Mesalamine has been associated with eosinophilic pneumonia when taken orally and when used as a suppository.[84] In addition to causing eosinophilic pneumonia, sulfasalazine has been reported to cause OP and NSIP.[12,85,86] There is one report of the development of sarcoid-like granulomatous hilar adenopathy in a patient with inflammatory bowel disease treated with sulfasalazine.[87] OP has been associated with mesalamine, as has hypersensitivity pneumonitis.[88,89]

D-Penicillamine

D-Penicillamine is used as an anti-inflammatory agent traditionally used in the management of RA, systemic sclerosis, primary biliary cirrhosis, lead poisoning, and Wilson's disease. D-penicillamine is a heavy metal chelating agent that has inhibitory effects on T lymphocytes, impairs fibroblast proliferation, and decreases levels of rheumatoid factor and immune complexes. Although currently used less frequently than first-line DMARDs, one still sees it used in the treatment of Wilson's disease and its pulmonary manifestations are important to recognize, as mortality from D-penicillamine pulmonary toxicity can be high.

Pulmonary toxicity ascribed to D-penicillamine is primarily reported in the older literature and includes pulmonary–renal syndrome with diffuse alveolar hemorrhage (DAH), obliterative bronchiolitis, acute interstitial pneumonitis, and hypersensitivity pneumonits.[90–92]

D-penicillamine is widely recognized as a cause of a number of autoimmune conditions, as well as nephrotic syndrome and rapidly progressive glomerulonephritis. It is less frequently a cause of a pulmonary–renal syndrome, with antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis and in some reports a clinical presentation similar to Goodpasture syndrome.[92–94] The pulmonary–renal syndrome occurs infrequently among patients on penicillamine therapy for rheumatic disease and is reported more often for those on D-penicillamine for Wilson's disease. Symptoms at presentation include cough, dyspnea, hemoptysis, and hematuria; onset has been reported from 10 months to many years after drug initiation. No definitive dose–response relationship has been defined, but there are reports of toxicity at doses as low as 300 mg per day and as high as 3.5 g per day. Coalescing, bilateral alveolar infiltrates characterize the radiographic findings, resulting in severe hypoxemia. BAL reveals an increase in the concentration of red blood cells on serial lavage and the presence of hemosiderin-laden macrophages, both of which characterize DAH. The diagnosis of D-penicillamine–induced ANCA-associated vasculitis with pulmonary renal syndrome is supported by high serum titers of antimyeloperoxidase (anti-MPO) antibodies; the presence of antinuclear antibody (ANA) is reported in 75% of cases. Although descriptions of "Goodpasture-like" syndromes due to D-penicillamine are reported, few actually had anti-GBM antibodies detected.[95]

The syndrome may progress to include respiratory and/or renal failure. Mortality from penicillamine-induced pulmonary–renal disease has been reported to be as high as 50%.

Drug withdrawal, accompanied by high-dose corticosteroids, is the cornerstone of therapy. Adjunctive treatment with plasma exchange, cyclophosphamide, and/or mycophenolate mofetil is often offered, although studies definitively supporting their use do not exist.

No specific risk factors have been identified for D-penicillamine–induced pulmonary–renal syndrome. Monitoring for subtle onset of respiratory symptoms is warranted with long-term use of D-penicillamine. It should be noted that ANCA seroconversion can occur without full manifestation of pulmonary–renal disease, and only a small proportion of those with drug-induced ANCA positivity will have clinically significant disease.[96]

■ Biologic Immunomodulatory Drugs

Immunomodulatory biologics are being used with increasing frequently for treatment of many illnesses including dermatologic conditions, inflammatory bowel disease, systemic rheumatic diseases, asthma, and malignancies. The increased use of biologics has resulted in a wide range of sequelae due to their use. Infections are common adverse events and are most frequently reported among patients on anti-TNF therapies. Clinicians are encountering a variety of autoimmune conditions that appear to be associated with the use of biologics.

The Study Group on Autoimmune Diseases of the Spanish Society of Internal Medicine has created the BIOGEAS registry of cases (*www.biogeas.org*), a compilation of the literature on cases of autoimmune diseases ascribed to the use of all categories of biologics.[97] In this registry of 12,731 cases of biologic-related toxicity reported in 2017, interstitial lung disease was less common (n = 518) than psoriasis (n = 6375), inflammatory bowel disease (n = 845), and demyelinating central nervous system disease (n = 803). The drugs implicated reflect the practice patterns at the time the registry was compiled, and we can expect the relative proportion of cases ascribed to various classes of biologics to shift based on the prevalence of their use.

Respiratory infections are the most common complications of DMARD treatment for RA-associated lung disease, most prominently seen among those on biologics. The clinician must carefully exclude infection before a diagnosis of drug-induced ILD can be considered, especially since biologics raise the risk of both acute bacterial and viral infections, as well as indolent pulmonary infections (e.g., tuberculous and nontuberculous mycobacterial and fungal). There are no specific recommended imaging or pulmonary function testing intervals, so a high index of suspicion for pulmonary sequelae of medication should be maintained, and clinical judgment should drive serial testing and invasive evaluations.

Among noninfectious pulmonary disorders associated with the use of anti-TNF therapies, interstitial pneumonitis is the most common manifestation of drug-induced disease. Interstitial pneumonitis was reported in 0.5% of 5000 Japanese subjects treated with infliximab and in 0.6% of over 7000 subjects who received etanercept.[98,99]

An analysis of 122 cases collected between January 1990 and March 2010 characterized the scope of these pulmonary adverse events associated with biologics.[100] The vast majority of cases were in patients with RA and were associated with anti-TNF medications (58 cases with use of etanercept, 56 cases in the setting of infliximab, 5 with rituximab, and 3 with adalimumab). Of these subjects, 10% had previously been prescribed other biologics and the majority had a history of use of nonbiologic DMARDS: 63% had a history of MTX use, and fewer had been treated with azathioprine (n = 5) or leflunomide (n = 3). Dyspnea was the predominant symptom of drug-induced ILD; 44% had fever and 39% had cough. Confirmatory biopsies were performed in a minority of cases with a fairly equal distribution of UIP, NSIP, and OP as the more common histopathologic patterns. In a systematic review of drug-induced or drug-exacerbated ILD among patients on biologics for RA between 1975 to 2013, there were 31 cases of TNF inhibitor–induced or –exacerbated ILD (14 with infliximab, 9 with etanercept, 5 with adalimumab, and 3 with certolizumab).[69] The same systematic review identified 5 cases of rituximab-associated lung toxicity (3 cases with concomitant methotrexate use) and 8 reports of tocilizumab associated lung toxicity, but since the precise prevalence of use of use of each drug is not known the risk associated with each agent is not determined.

Etanercept

Of the noninfectious adverse effects of etanercept therapy, sarcoid-like reactions and new-onset ILD or progression of underlying ILD feature prominently in the pulmonary literature. ILDs related to use of anti–TNF-α agents have been reported more frequently in women (3:1 female:male) often in the sixth decade. Various patterns of ILD are reported including NSIP, UIP, OP, DAD, and sarcoid-like reactions, and most have lymphocytosis on BAL (Fig. 65-2).

In a large case series of autoimmune disease induced by TNF antagonists, 24 cases of interstitial pneumonitis were noted among 233 subjects studied.[101] In a review summarizing case series and reports published between 1990 and 2010, the mean time of onset of respiratory symptoms for subjects receiving biologic was 26 weeks, with 50% of cases occurring within the first 2 months.[102]

Sarcoid-like granulomatosis has been frequently reported with the use of anti-TNF agents. Etanercept (9 cases), infliximab (5 cases), and adalimumab (1 case) have been reported to trigger sarcoid-like reactions with symptoms of cough, chest pain, and

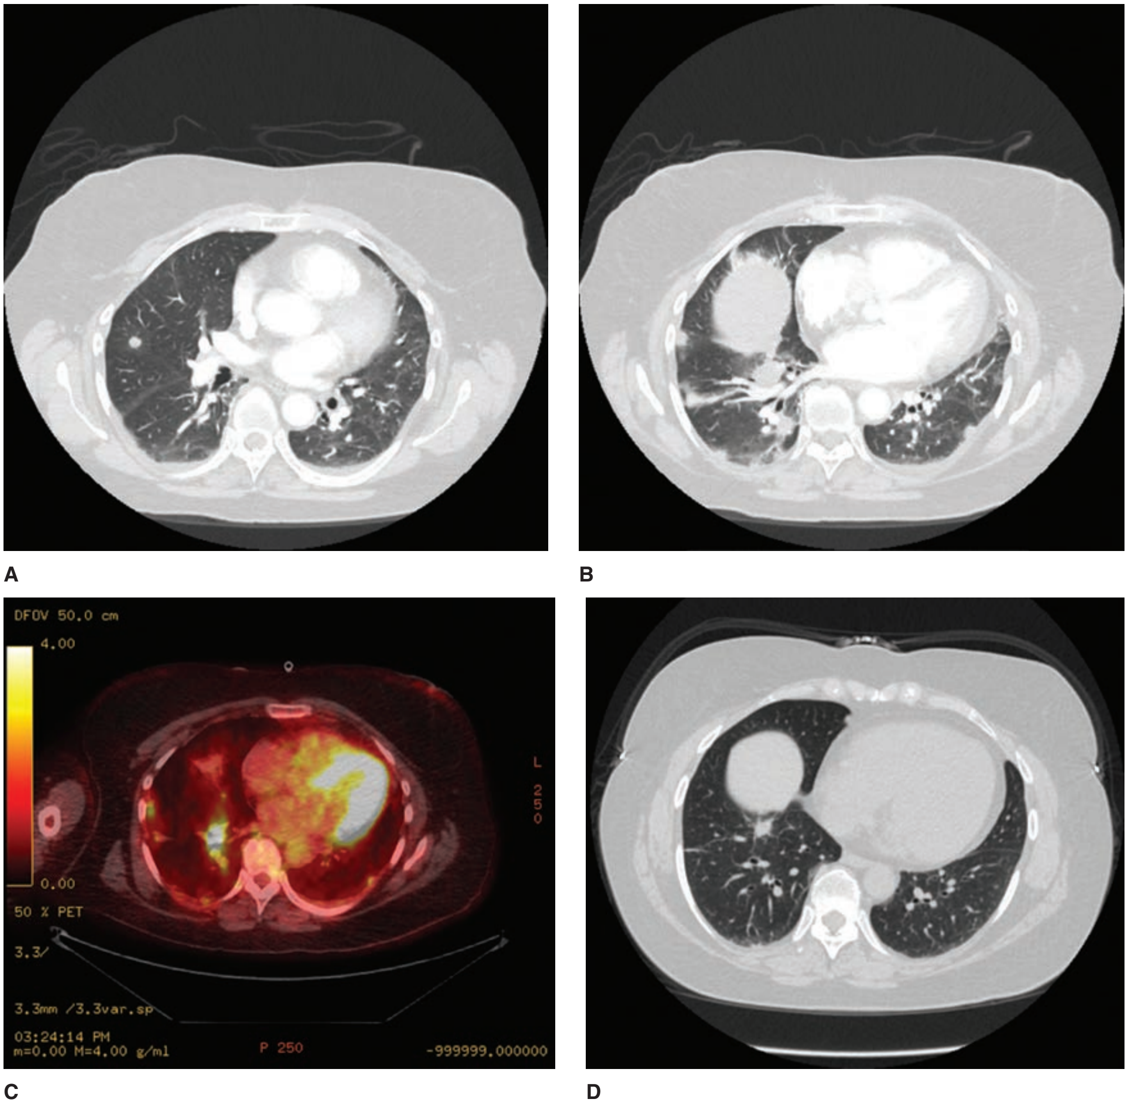

Figure 65-2 Etanercept toxicity in a 55-year-old woman with onset of pustular skin lesions 3 weeks after initiation of etanercept for psoriasis followed by dry cough, fatigue, and progressive dyspnea. **A, B.** Nodular opacities bilaterally. **C.** PET/CT showing FDG-avid nodules at same level as image **B. D.** Near-complete resolution of nodules 5 weeks after discontinuation of etanercept, and a course of prednisone.

dyspnea and lung findings most commonly including hilar and/or mediastinal adenopathy and less frequently pulmonary nodules or infiltrates.[103] Noncaseating granulomas are documented on biopsies. The subjects in whom these reactions were seen were under treatment for RA, ankylosing spondylitis, psoriatic arthritis, or juvenile idiopathic arthritis. Nonthoracic sites of sarcoid involvement were also seen as parotid enlargement, skin manifestations, and neuro-ocular disease. The sarcoidosis resolved with cessation of the drug in the majority, and in some cases corticosteroids were used. This suggests an apparently paradoxical class effect of TNF-α blockade, as these agents have been used in the treatment of refractory sarcoidosis. The mechanism of granuloma formation in the context of anti-TNF therapy is not understood but appears to derive from complex dysregulatory effects of TNF-α blockade. Among cases of sarcoid-like disease, 50% were compatible with stage 2 sarcoidosis, and two-thirds of all cases resolved with discontinuation of biologic therapy.[102]

TNF-α inhibitors, especially infliximab, have been implicated as a cause of mild lupus-like syndromes with positive ANA and anti-dsDNA, with some patients exhibiting rash, serositis, or oral ulcers, but none of the 14 patients in one series had significant respiratory system manifestations of lupus.[104] More recently the British Society for Rheumatology Biologics Register–Rheumatoid Arthritis reviewed a cohort of 12,937 of subjects started on TNF therapy compared with a biologic-naïve cohort treated with nonbiologic DMARDs (nbDMARD, n = 3673). This study found that the addition of a TNF-α inhibitor did not increase the risk of lupus-like or vasculitis-like events over the risk from nbDMARD therapy. The risk for both cohorts was calculated at 10/10,000 patient-years.[105] In one case report there was histologic demonstration of OP in small nodular opacities that appeared 16 months after etanercept as sole therapy for RA that had previously been poorly controlled with nbDMARDs.[106] The patient presented with shortness of breath and joint swelling and tenderness of her hands and wrists with a positive ANA at 1:2560, in a speckled pattern, and 1:640 in a homogenous pattern. Thus, manifestations of a lupus-like condition can be concurrent with lung toxicity, but overall, lupus-like or vasculitis-like events due to TNF-α blockade are not a major concern for the pulmonologist.

Adalimumab

Adalimumab, a TNF-α antagonist used in management of RA, also has been reported to cause pulmonary toxicity. Reports indicate lung injury occurring months to years into therapy. Patients usually present with dyspnea, cough, and radiographic and histologic findings consistent with interstitial pneumonitis and OP.[107] Acute onset of lung injury has reported within 1 h of dosing of this agent.[108] Symptoms may begin subtly as mild cough following a treatment cycle and progress with each subsequent injection. Imaging shows patchy ground-glass opacities, with or without consolidation and patchy fibrosis.[109] Patients usually require corticosteroids to achieve clinical resolution.

Rituximab

Rituximab is a CD20-directed, B cell–depleting monoclonal antibody used in the treatment of a variety of conditions including RA and RA-ILD, granulomatosis with polyangiitis, microscopic polyangiitis, systemic sclerosis, and lymphoma. A number of case reports regarding its pulmonary toxicity appear in the literature, with clinical presentations ranging from dyspnea and mild hypoxemia to fatal respiratory failure.[110] Clinical disease occurs in three different time courses, most commonly as a subacute onset of dyspnea 2 weeks following rituximab infusion, often several cycles into therapy. Radiographic imaging shows bilateral diffuse interstitial infiltrates or ground-glass opacities. Less common presentations include acute onset of ARDS within hours of first infusion of the drug and chronic, insidious onset of disease.[111] In a prospective series of 33 patients with RA treated with rituximab over 26 weeks, 22% of subjects developed subtle decline in $\mathrm{DL_{CO}}$ without respiratory symptoms, and none developed overt lung toxicity. Importantly, however, despite these reports of adverse events, rituximab has been found to stabilize or improve lung disease in patients with RA-ILD, and the safety profile is deemed to be acceptable.[70,112]

Patients who are being considered for initiation of new medications should have baseline radiologic imaging and pulmonary function testing to ascertain whether pre-existing lung disease is present. While pre-existing lung conditions are not a contraindication to therapy, patients need to be monitored for changes in symptoms that might reflect either medication-induced disease or progression of the condition for which medication is being prescribed. This is particularly relevant for RA where new or progressive RA-ILD must be distinguished from drug-induced ILD.

■ Immunosuppressants

Sirolimus and everolimus are immunosuppressive agents used in the management of patients with solid organ transplants and are used in the treatment of malignancies including breast cancer. They function as inhibitors of mammalian target of rapamycin (mTOR) and suppress organ rejection through inhibition of growth factor–induced smooth muscle cell proliferation and migration; they also inhibit T- and B-cell activation.

Sirolimus was introduced into clinical use in the late 1990s. Sirolimus-induced pneumonitis in solid organ transplant recipients is an important consideration in the differential diagnosis of dyspnea with interstitial infiltrates after exclusion of infection. Case reports of sirolimus-induced pulmonary toxicity began to appear in the literature in 2000, when the drug was first implicated as the cause of biopsy-proven bronchiolitis obliterans organizing pneumonia in a renal transplant recipient. Other case series have appeared since, with a variety of radiographic patterns including patchy peripheral consolidations consistent with OP as well as reticular and ground-glass opacities, and histology showing lymphocytic alveolitis and interstitial pneumonitis, granulomatous inflammation, alveolar hemorrhage, and/or focal fibrosis.[113,114]

A dose–response relationship is suggested for mTOR inhibitor–induced pulmonary toxicity, because dose reduction appears to ameliorate the pneumonitis. Toxicity may occur despite therapeutic serum sirolimus levels and can occur as early as 2 weeks into therapy, but it occurs more often after at least 6 weeks of therapy. The overall incidence of sirolimus-induced lung injury is 5% to 15% in solid organ transplant recipients.[115] Discontinuation of sirolimus is necessary for syndrome resolution. Complete recovery is typically achieved in all patients by 6 months.

Everolimus has been shown to cause mild, reversible pulmonary toxicity. In a large case-cohort study of renal transplant recipients on everolimus, mild lung toxicity was observed in 13 of 102 patients (12.7%).[115] The typical presentation was cough and dyspnea, and diagnosis was established at a median time of 162 (38–407) days since onset of treatment. Radiologic findings were most consistent with OP, and fewer with NSIP or a combination of patterns. All cases resolved with discontinuation of everolimus, and only 3 patients required steroids for resolution.

■ Antimicrobials

The most commonly reported respiratory syndrome for all classes of antimicrobials is pulmonary infiltrates with PIE. Among the reports of antibiotic-associated PIE syndrome are many cases of minocycline- and erythromycin-induced PIE, and fewer cases associated with penicillins, tetracyclines, sulfonamides, and cephalosporins. Cases of PIE have also been reported with the use of antituberculous drugs, including isoniazid, rifampin, and ethambutol.

Nitrofurantoin

Nitrofurantoin is one of the most commonly implicated antimicrobial agents that causes pulmonary toxicity. Although its peak usage worldwide was probably in the 1980s, it remains a widely used antibiotic for management of chronic urinary tract infections, and case reports continue to appear in the literature. Since the drug is used primary in the elderly population in whom cardiopulmonary disease is common, the differential diagnosis of respiratory compromise in this population is broad. The incidence of nitrofurantoin lung toxicity with short-term use (≤14 days) is very low; in one meta-analysis of 27 studies of 4807 patients there were no cases of pulmonary toxicity.[116] Long-term use of nitrofurantoin for prophylaxis against recurrent urinary tract infections is associated with high risk of nonsevere adverse events, and the risk of severe pulmonary toxicity appears to increase with longer duration of therapy; one meta-analysis reported only 1 case of significant interstitial pneumonitis among 511 patients, which occurred at 37 months of therapy.[117]

There is a wide clinical spectrum of respiratory disease caused by nitrofurantoin. As is the case with many types of drug-induced lung toxicity, the onset of symptoms is highly unpredictable and of variable latency. The severity of disease varies, and the histopathology is diverse. Most of the earliest reported cases of nitrofurantoin pulmonary toxicity were acute in onset, occurring within days to weeks of treatment initiation. These patients presented with fever (80%), cough (43%), dyspnea (60%), rash (20%), fatigue (12%), and arthralgias (9%). Peripheral blood eosinophilia is present in 80%.[118] As reports of toxicity have continued to populate the literature, it has become clear that subacute and chronic presentations also are common (Fig. 65-3).

Unfortunately, many cases of nitrofurantoin lung toxicity may be missed due to the long latency between the initial dose and the onset of clinical symptoms. The median time to diagnosis in one series was 4 months; however, some diagnoses were made as long as 5 years after drug initiation. Among those with chronic symptoms, the most common histopathologic pattern is that of chronic interstitial pneumonitis, with fewer reported cases of bronchiolitis obliterans organizing pneumonia and granulomatous interstitial disease. High-resolution CT findings in 18 patients with chronic nitrofurantoin lung injury showed bilateral ground-glass opacities in all subjects (diffuse in 30%, and with a middle to upper lung zone predominance in 40%). Irregular linear opacities were present

AL GRAWANY

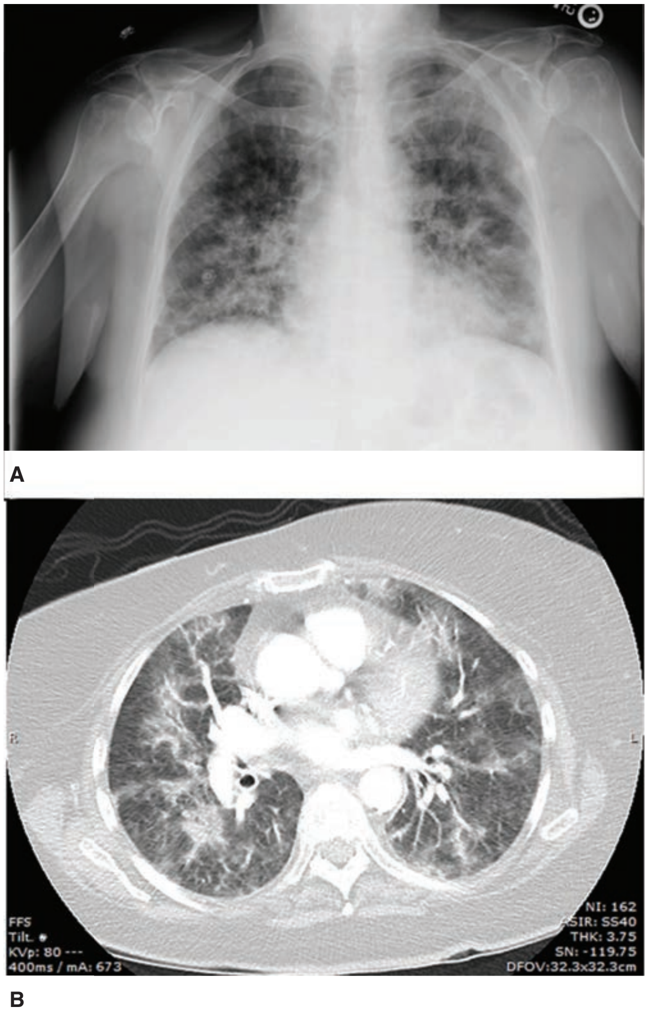

Figure 65-3 Nitrofurantoin-induced organizing pneumonia. **A.** Chest radiograph of an 80-year-old woman 1 year after initiation of nitrofurantoin for recurrent urinary tract infection. **B.** CT scan showing patchy ground-glass opacities and consolidation consistent with nitrofurantoin-induced organizing pneumonia.

in 30%, consolidation in 30%, and traction bronchiectasis in 10% (one subject).[119] Many other histopathologic patterns and clinical syndromes have been reported as associated with nitrofurantoin use, including pulmonary edema, ARDS, vasculitis, DAH, SLE, PIE, and nodules.

Interferons

The high prevalence of chronic hepatitis C worldwide and its treatment with pegylated interferon-alfa-2a has brought with it reports of systemic and pulmonary toxicity. The significant systemic side effect profile associated with interferon therapies has increased the enthusiasm for regimens of direct-acting antivirals (DAA), but their prohibitive cost limits the use of DAA in under-resourced settings. Systemic side effects are common among patients treated with interferons, typically including flu-like symptoms of fatigue, headache, anorexia, and myalgias, but pulmonary symptoms occur relatively infrequently. Ribavirin, a synthetic nucleoside analogue, is often used in conjunction with interferons to enhance their antiviral activity. Ribavirin is associated with dyspnea and cough, but it has not been reported to cause pulmonary toxicity when used alone.

Interferon-induced lung toxicity is usually in the form of interstitial infiltrates, pulmonary sarcoidosis, OP, and/or pleural effusion. The mean time from treatment onset to lung disease presentation is 11.8 weeks (range, 2–48 weeks).[120] The reported rate of pulmonary interstitial disease and/or OP is as high as 6% among patients receiving high-dose daily interferon for hepatitis C, and <1% among patients on conventional three-times-weekly dosing schedules of interferon and ribavirin.[121] Most cases of interferon pulmonary toxicity resolve fully with discontinuation of the medications.[120]

Several case reports or small series of cases characterize the association of de novo sarcoidosis or recrudescent sarcoidosis with interferon-α and interferon-α_2 a used in chronic hepatitis C.[122] The incidence of sarcoidosis among patients receiving interferon is not well established but has been reported to be as high as 5% among patients receiving treatment with interferon-α_2 a for hepatitis C.[123] Interferon-associated pulmonary sarcoidosis occurs along with involvement of other sites, including cutaneous, parotid, liver, ocular, and cardiac involvement. Prompt withdrawal of the drug is advised, and corticosteroids may be necessary for disease resolution.

■ Opiates and Illicit Drugs

Complications of illicit drug use are numerous and encompass toxic injury to the lung related to use of the drug itself, and the associated infectious sequelae of venous cannulation, including endocarditis and septic embolization. The prevalence of tuberculosis among drug users puts these individuals at high risk of active tuberculosis as well. Opiates or other sedatives may cause altered mental status and impairment of the gag reflex, substantially increasing the risk of aspiration pneumonia. Pulmonary parenchymal disease may also be caused by talc or other inert substances used to “cut” the drugs. Recognition of these conditions, unrelated to direct toxicity of the drug, broadens the differential diagnosis of respiratory symptoms in users of illicit drugs.

Heroin

Overdoses of heroin and other narcotics cause respiratory depression through stimulation of the μ-opioid receptor in the brainstem and can also result in pulmonary edema as a contributor to respiratory failure. One of the earliest reports of drug-induced lung disease was by Osler in 1880, in which he described pulmonary edema in an opiate addict and ascribed the edema to the opiate use. The frequency of heroin-induced pulmonary edema (HIPE) has been reported to be as high as 50% of subjects with heroin overdose and as low as 2.1% of cases.[124] In the latter series, one-third of the patients required intubation and mechanical ventilation, but the hypoxemia of HIPE resolved within 48 h of presentation. In fatal opioid overdoses, autopsies show pulmonary edema in the large majority of cases. It is likely that the edema occurs due to increased vascular permeability as evidenced by the higher protein content in the pulmonary edema fluid of opioid overdose compared with cardiogenic edema.[125] Shifts in vascular hydrostatic pressure in the setting of myocardial depression also may contribute, as would negative pressure pulmonary edema from respiratory efforts against an obstructed upper airway from opioid-provoked upper airway collapse in subjects with sleep apnea.

Heroin use can also cause acute bronchospasm.

Pulmonary disease associated with illicit injection drug use may be unrelated to the drug itself. Talc used to cut heroin or methadone, or other inert substances used in narcotic pills that are crushed and injected, can produce foreign-body granulomatous reactions in the pulmonary vasculature and interstitium. Characteristic radiographic findings consist of a diffuse, micronodular pulmonary infiltrate that evolves into coalescent conglomerates, often in the upper lobes, similar in appearance to that of progressive massive fibrosis. These alterations may be accompanied by emphysematous changes in the lower lobes, which may result in pneumothoraces.

Other pulmonary complications of injection drug use include septic emboli, abscess formation, bronchiectasis, and bullae independent of apical fibrotic reactions.

Cocaine

Cocaine is typically smoked as "crack" cocaine, an alkaloid derivative of cocaine hydrochloride that is mixed with ether or alcohol. Respiratory symptoms typically develop acutely, within hours of use, and include cough, hemoptysis, chest pain, and shortness of breath. Bronchospasm, which may be severe enough to precipitate respiratory failure, has been reported with and without a prior history of asthma. The radiographic appearance may be consistent with ARDS, and the histopathology is that of DAD, with or without alveolar hemorrhage that may be diffuse or focal.[126,127] Talcosis can occur as a result of cocaine inhalation and can be associated with spontaneous pneumothorax.[128]

PRINCIPLES OF TREATMENT AND DISEASE RESOLUTION

Prompt recognition of drug-induced lung disease will allow patients the greatest chance of clinical and radiographic recovery before irreversible lung injury occurs. In most cases of drug-induced pulmonary injury, discontinuation of the culprit drug is sufficient for regression of clinical symptoms and most of the radiographic findings. The decision to treat with corticosteroids must be individualized, based on the severity of the clinical picture and the expected rapidity of symptom resolution. For example, amiodarone pulmonary toxicity frequently requires oral corticosteroid administration unless the symptoms are very mild, because of the long serum half-life of the drug. Recrudescence of lung injury is rare among implicated drugs in the absence of re-exposure to the culprit drug. Overall, corticosteroids are used with apparent success, but controlled studies to determine therapeutic efficacy are lacking, and the infrequent occurrence of most drug toxicities will not allow this treatment to be convincingly studied in clinical trials.

CHAPTER 66

Lung Injury Associated with Recreational Drug Use

Timothy E. Albertson
Patrick Mangialardi
James A. Chenoweth
Susan Murin

INTRODUCTION

Recreational drugs (RDs), sometimes called drugs of abuse or illicit drugs, are commonly used in many societies worldwide. Not all recreational drugs are illegal, but all are capable of being abused. The Australian Government estimates that in 2019, 43% of its citizens had illicitly used a drug in their lifetime, while 16.4% had used one during the prior 12 months.[1] According to the European Monitoring Center for Drugs and Drug Addiction, the estimated prevalence of illicit drug use in 2017 to 2018 in the general population of England and Wales, as assessed by survey, is similar to a decade ago, with 1 out of 10 adults aged 16 to 59 years confirming use within the last year.[2] As of 2016, almost 119 million people in the United States had used marijuana in their lifetime.[3] The same report noted that about 39 million Americans had used cocaine, 9 million had used crack cocaine, 5 million had used heroin, 18 million had used Ecstasy, and 15 million had used methamphetamine. The Global Drug Survey estimates that 64% of the global population has used an illicit drug at least once.[3]

Recreational and illicit drugs of abuse are associated with health complications that affect many different organs. It is not surprising that admissions to emergency departments and hospitals and health-care utilization in general are several times higher for adults who use illicit drugs.[4] Table 66-1 outlines potential respiratory systems adverse effects or complications associated with the use and misuse of recreational drugs. The potential respiratory system anatomic areas of insult by recreational drugs can be divided into oral/airways, pleural space/extrapulmonary, pulmonary vasculature, and lung parenchyma/alveolar space.

These pulmonary complications can result from an overdose of RDs, as a result of the dosing approach or route used, or as an effect of the drug itself.[5] The pulmonary complications of drug use/abuse can also be classified as either infectious or noninfectious.[6] Infectious complications are common, and include typical respiratory pathogens as well as tuberculosis,[7] skin abscesses, endocarditis, and septic emboli to the lung. Mechanical noninfective and foreign body complications of RD use can be significant, as can the effects of inhalation or intravenous use of RD that have been diluted or "cut" with talc (hydrated magnesium silicate) or other foreign materials.

Recreational drug use in some vulnerable populations is thought to provide a "double hit" that may worsen underlying pathology, such as in patients with human immunodeficiency virus (HIV) who use intravenous heroin or methamphetamine. They appear to be at greater risk of developing pulmonary hypertension and have a higher associated mortality than do non-drug-using HIV patients.[8]

This chapter primarily focuses on the pulmonary toxicity and injury associated with the RDs and drugs of abuse, including marijuana, cocaine, methamphetamine and derivatives, and heroin/opioids. It will also review the pulmonary complications associated with volatile substance misuse.

METHAMPHETAMINE AND AMPHETAMINE DERIVATIVES

Methamphetamine, its metabolite amphetamine, 3-4-methylenedioxy-methamphetamine (MDMA, "Ecstasy"), and cathinone derivatives ("Bath Salts") all share related chemical structures and some toxicities (Fig. 66-1). These drugs are often used as RDs, and most are considered illicit drugs of abuse. A number of toxic manifestations affecting the respiratory system have been described as a result of their use, illicit manufacturing or processing, and overdose.

Methamphetamine use was associated with more acute hospital admissions in California between 1990 and 2005 for RDs than all

other RDs except alcohol.[9] Higher adjusted mortality rates were also seen with methamphetamine-related admissions. Table 66-2 provides a summary of the pulmonary toxicity reported with the use of these drugs. Methamphetamine use is common worldwide with some regional variation. Both MDMA and the cathinone derivatives have lower prevalence but are also used worldwide. The various reported respiratory system effects are discussed below, according to the anatomic area affected.

■ Upper Respiratory Tract/Airway

"Meth-mouth" can occur both as a result of illicit manufacturing and the repeated use of methamphetamine.[10] "Meth-mouth" consists of poor dental hygiene, xerostomia, dental caries, and excessive tooth wear. In IV methamphetamine users compared with matched non-users, tooth decay rates were significantly ($p= 0.04$) higher in the user group. Methamphetamine users have a distinctive pattern of tooth surface wear with carious surface involvement highest on the maxillary central incisors, followed by maxillary posterior premolars and molars.[11] In addition to grinding of teeth and oral exposure to solvents during manufacturing, methamphetamine users had higher levels of sugary beverage consumption compared to controls.[12] These changes were not dependent on dose or route of methamphetamine use. The oral findings of poor dentition not only act as indicators of methamphetamine use but also likely increase the risk of lung infections, given known associations between poor dentition and respiratory infections.

■ Pleural Space/Extrapulmonary/Barotrauma

Spontaneous or nontraumatic pneumomediastinum, pneumothorax, pneumopericardium, and diffuse subcutaneous emphysema have been reported after IV, snorted, and inhaled methamphetamine use[13,14] and after inhaled, snorted, and oral use of Ecstasy or MDMA.[15–23] The use of the cathinone derivative mephedrone was associated with a pneumomediastinum after inhalation.[24,25] This barotrauma results from sudden increases in intrathoracic pressures and intra-alveolar pressures generated during snorting, exaggerated inhalations (including inhalation of heated drugs) and "Valsalva-like" maneuvers performed by users. Some users do almost ritualistic forced Valsalva maneuvers after snorting or smoking methamphetamine or amphetamine derivatives. The mechanism by which methamphetamine, Ecstasy, or cathinone derivatives cause barotrauma when the agents are taken intravenously or orally may be due to coughing or retching. Based on the numbers of case reports of barotrauma, it does appear to be a real complication of the use of recreational methamphetamine and amphetamine-like compounds via these routes of administration. The actual incidence and risk of barotrauma are not known.

■ Pulmonary Vasculature

The recreational or illicit use of methamphetamine has been associated with the development of pulmonary hypertension. In studies in mice, methamphetamine/amphetamine inappropriately enhances mitochondrial oxidative phosphorylation and pulmonary artery DNA damage associated with hypoxia and pulmonary artery vascular remodeling thought to be a contributor to the development of pulmonary hypertension associated with the use of methamphetamine and its derivatives.[26] Using rats, Liu et al.[27] found that the serotonin uptake inhibitor fluoxetine given with methamphetamine attenuated pulmonary artery remodeling that is associated with pulmonary hypertension. Fluoxetine also downregulated the protein expression of the serotonin transporter protein and serotonin (5-HT_{IB}) receptor both of which are normally increased with methamphetamine exposures.

The incidence of methamphetamine and its derivatives inducing pulmonary hypertension in recreational users is unknown, but it does appear to be common and associated with an aggressive form of pulmonary hypertension. Pulmonary hypertension associated with recreational methamphetamine use and the therapeutic use of amphetamine-like anorectic drugs has been reported with or without foreign body granuloma formation.[28–35] In a case series of 90 patients with pulmonary hypertension associated with methamphetamine use compared to 97 patients with idiopathic pulmonary hypertension, the methamphetamine patients had worse outcomes and more severe pulmonary hypertension.[35] Zhao et al. similarly found that both methamphetamine-associated pulmonary hypertension and cardiomyopathy were associated with an increased mortality risk.[29]

TABLE 66-2 Pulmonary Toxicity Associated with Methamphetamine and Amphetamine Derivative Use

Toxic Effect

Foreign body embolism
Lung parenchyma/alveolar space
• Pulmonary edema
Noncardiogenic
ARDS
Cardiogenic
• Pulmonary infection
Pneumonia
Bronchitis
• Alveolar hemorrhage

■ Lung Parenchyma/Alveolar Space

Noncardiogenic pulmonary edema including acute respiratory disease syndrome (ARDS) has been reported rarely after the recreational or illicit use of methamphetamine.[36–38] Considering the frequency of the use of methamphetamine and its derivatives, only a relatively few cases have been noted, suggesting this is an infrequent complication. The mechanisms of noncardiogenic pulmonary edema are not known but could include direct toxic effect of the drug or its metabolites, or the thermal products or toxic gas byproducts of the manufacturing process. An example of the latter can be seen in the deaths with severe pulmonary edema of three people manufacturing methamphetamine in a hotel room where they were exposed to phosphine gas that was accidentally generated through the heating of red phosphorous in the presence of acids.[36] Other than direct toxic effects on the lung, other proposed mechanisms include neurogenic pulmonary edema (from sympathetic vasoactive effects of methamphetamine or from methamphetamine-generated seizures), attempted inspiration against a closed glottis (negative-pressure pulmonary edema), or aspiration of gastric contents.[5]

Cardiogenic pulmonary edema is seen in acute but more commonly in chronic users of methamphetamine who develop decompensated heart failure from methamphetamine-associated acute or chronic cardiomyopathy.[29,39–41] Catecholamine excess is thought to be a major cause of this cardiomyopathy.[41] Additionally, amphetamines can stimulate heart rate, expired carbon dioxide (CO_2), and inspiratory drive in rats in a dose-dependent manner.[42] Standard treatments for noncardiogenic and cardiogenic pulmonary edema including noninvasive or invasive ventilation with positive end-expiratory pressures, avoidance of toxins, diuretics, and afterload reducers are used. The careful use of beta blockers also can be considered.

A case report of diffuse alveolar hemorrhage following inhalation of a synthetic cathinone has been reported.[43] Cathinone and methcathinone have been used and abused as RDs since the early 1990s.[44] More recently, a variety of synthetic cathinones have been reported and are responsible for episodic outbreaks of toxicity in western Europe and the United States.[45]

In the study of hospitalizations between 2005 and 2011 in California, methamphetamine use was found also to be associated with increased risk of hospitalization for pneumonia, acute respiratory failure, and exacerbations of COPD.[46] A wide range of other reports have noted pulmonary toxicities including foreign body pulmonary granulomas associated with nasal inhalation[47] and intravenous use of methamphetamine.[28] Nasal inhalers of amphetamine and amphetamine derivatives have been broken apart, dissolved, and used intravenously, generating pulmonary granulomas.[48] Severe emphysema has also been reported with the IV use of crushed methylphenidate pills in several young patients.[49,50] A case of "speed-balling" or taking simultaneously a stimulant (methamphetamine) and heroin intravenously reported needle embolization into the right ventricle with numerous foreign body granulomas in the lung.[51] The frequency of these complications of amphetamine RD use has not been determined but seems rare.

OPIOID-ASSOCIATED LUNG TOXICITY

Opioids are a common RD. Figure 66-2 gives the chemical structures of some common opioids. There are multiple routes for the recreational use of opioids including snorting, skin popping, IV administration, oral ingestion, and inhalation. Acute opioid use reduces respiratory drive and the sensation of dyspnea in a dose-dependent manner subject to tolerance.[52] Respiratory drive is generated from the respiratory center located in the pons and medulla of the brain and is stimulated by increases in blood CO_2, and decreases in oxygen and pH. With reduction of respiratory drive by opioids, changes in arterial CO_2 content and pH that would normally stimulate increases in minute ventilation fail to generate a response. In general, the opioid antagonist naloxone reverses this opioid-induced blunted response to arterial CO_2 and reduced pH. Patients with pre-existing elevated arterial partial pressures of CO_2 (Pa_{CO_2}) such as those with obesity-hypoventilation or severe chronic obstructive pulmonary disease (COPD) may be more sensitive to opioid-induced respiratory depression. Table 66-3 summarizes major reported respiratory system toxicities with opioid use, which are further discussed below.

■ Upper Respiratory Tract/Airway

Opioid use has been associated with a variety of airway-related disorders. One case series describes nasal perforations with nasal insufflation of acetaminophen/hydrocodone. Another describes a case of septal, soft palate, and sinus necrosis with insufflation of oxycodone.[53] Cough and bronchospasm associated with opioid use are thought to be due to allergic reactions and/or histamine-releasing processes.[52,54,55] Both the smoking of heroin and opium and the intravenous use of heroin have been associated with acute bronchospasm in both asthmatics and nonasthmatics.[53,56] Inhalation of heroin was shown to be associated with an increase in asthma exacerbations in case series, case-control trials, and retrospective cohort analysis.[57] Heroin users also were found to require intubation more frequently during asthma exacerbations than non-users (17.0% vs. 2.3%, respectively; $p = 0.0036$).[58] Among 512 heroin users on methadone maintenance therapy, with a mean age of 26.8 ± 1.0 years, 6% were found to have obstructive changes attributed to asthma or chronic bronchitis and 7% had restrictive changes due to interstitial lung disease.[59] A total of 190 subjects (38%) had low diffusing capacity of the lungs for carbon monoxide (DL_{CO}), with most having normal lung volumes and spirometry. Foreign

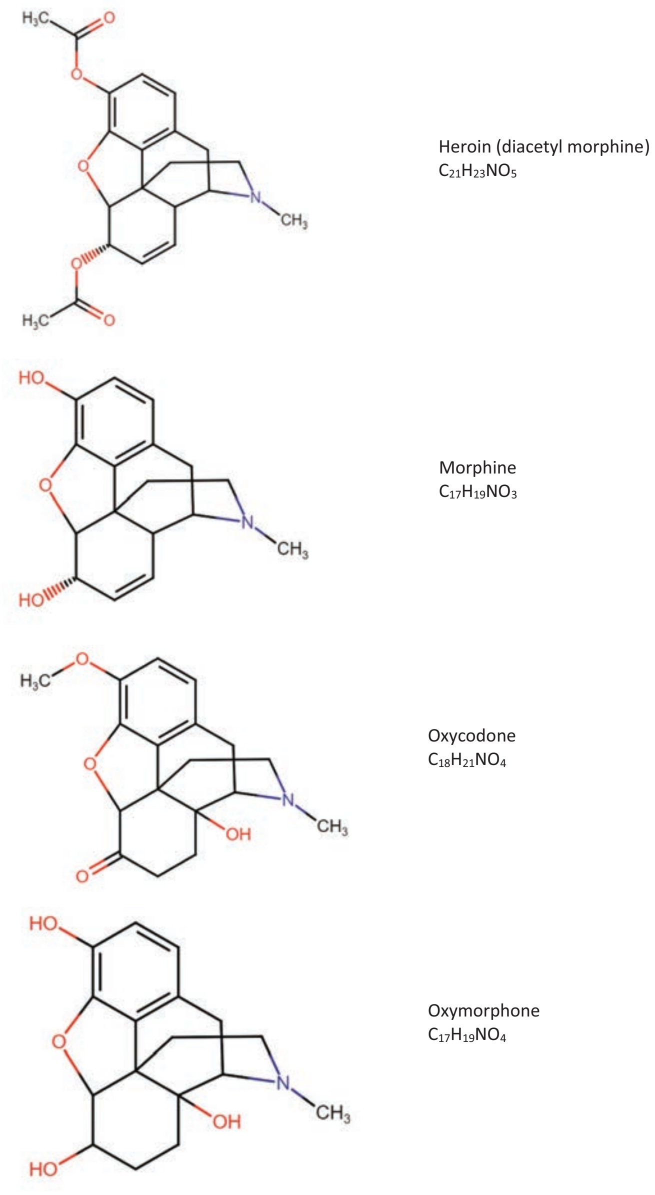

Figure 66-2 Heroin, morphine and oxycodone chemical structures.

TABLE 66-3 Recreational Opioid Use Pulmonary Toxicity

Toxic Effect
Upper respiratory tract/airway
• Cough/histamine release/bronchospasm
• Worsening obstructive sleep apnea
• Asthma exacerbations
• Nasal septum perforation
• Vocal cord paralysis
• Bronchiolitis and airway obstruction
Barotrauma/pleural space/extrapulmonary
• Wooden chest syndrome—rigid thorax
• Pneumothorax
Pulmonary vasculature
• Foreign particle embolization
• Septic pulmonary emboli
Lung parenchyma/alveolar space
• Acute respiratory distress syndrome/noncardiogenic pulmonary edema
• Lung cancer
• Pneumonia (aspiration and non-aspiration)/immune modulation
• Pulmonary hemorrhage
• Atelectasis
• Granulomatous change
• Tuberculosis
• Eosinophilic pneumonia
• Pulmonary bullae
• Alveolar proteinosis

particle emboli were thought to be the cause of the reduced DL_{CO}.[59] A 2002 study that described pulmonary function tests in methadone maintenance patients found reduced forced expiratory volume in 1 second (FEV_1) compared with non-users, but these patients were more often tobacco smokers. A 2011 trial of heroin drug users maintained on inhaled heroin showed no change in spirometry over 10 months.[53] Another study of 161 current or former heroin smokers (122 [75.8%] had also smoked "crack" cocaine) found that they experienced an increased burden of respiratory symptoms and a greater decline in FEV_1 over 18 to 24 months than tobacco smokers with COPD and healthy non-smokers.[60]

Upper lobe large bullae were reported in 24% of a case series of opium smokers in one study from Singapore.[61] Bronchiolitis and airway obstruction also were seen in these patients, which may be the mechanism for development of such bullae.

■ Pleural Space/Extrapulmonary/Barotrauma

Pneumothorax and pneumomediastinum have been reported with recreational opioid use.[53,56,62] The causes range from mechanical consequences of using the supraclavicular fossa IV approach ("pocket shot") to other causes independent of the IV approach. This includes a case of bilateral pneumothoraces associated with septic emboli from right-sided endocarditis.[56] Another complication of the "pocket shot" reported in IV heroin users is vocal cord paralysis which can be unilateral or bilateral. It can present immediately or later as the consequence of neck abscess.[53]

Rapid death from opioid use can involve more than just respiratory drive suppression. Fentanyl-induced chest wall muscle rigidity (wooden chest syndrome) is well described in the anesthesia literature.[63,64] It is concerning due to the fact that wooden chest syndrome is not readily reversible by naloxone.[65] With the increased use of fentanyl as a drug of abuse on the streets and a marked increase in reported deaths despite increased availability of naloxone in the community, it has been postulated that wooden chest syndrome is a contributing factor.

■ Pulmonary Vasculature

Foreign body talc granuloma formulation in the pulmonary vasculature has been noted with resulting pulmonary hypertension in IV heroin users.[66] Similarly, talcosis occurs with inhalation of heroin cut with talc. In a study comparing talc granuloma formation in inhaled or IV heroin users, 11 cases demonstrated the mean lung talc particle size to be 3.7 ± 2.9 μm for those who inhaled heroin and 14.2 ± 9 μm ($p < 0.01$) for those who injected heroin.[66] As noted earlier, septic emboli from right-sided endocarditis is a major problem associated with IV heroin use. Septic pulmonary emboli can generate multiple endovascular and parenchymal abscesses in the lung.

Lung Parenchyma/Alveolar Space

The lung parenchyma and alveolar space are frequent sites of toxicity among opioid users. Opioid-induced noncardiogenic pulmonary edema was first described by Osler in a patient with morphine overdose and has since been observed with morphine, heroin, codeine, methadone, and fentanyl overdose.[52] Evidence of pulmonary edema is reported in 95% of autopsy cases and in 94% (opioids excluding fentanyl) and 96% (fentanyl) of opioid overdose post-mortem CT scans.[67,68] Aspiration was thought to have occurred in 68% of patients in the CT series and may have contributed to the development of pulmonary edema.[68] The sudden rise in fentanyl and fentanyl analogue use has led to many related deaths in opioid-tolerant heroin users and in non-heroin users.[69,70] Cases of opioid-induced noncardiogenic pulmonary edema including ARDS have been severe enough to require extracorporeal membrane oxygenation therapy.[71]

There are multiple other pulmonary parenchymal complications among opiate users. Poor respiratory effort associated with opioid-induced toxicity can lead to pulmonary atelectasis.[62] Patients with opioid overdoses with and without aspiration of gastric contents can develop pneumonia. A case of heroin inhalation with a Valsalva maneuver is thought to have resulted in acute pneumonitis.[72] Two cases of pulmonary hemorrhage were reported following acute heroin overdoses.[73] Additional, even more rare, lung complications have been reported such as the case of a person who smoked fentanyl patches for 3 months developing chest pain, fevers, night sweats, shortness of breath, weight loss, and malaise with bilateral crackles. Chest CT showed bilateral, extensive central lobular nodularity with focal septal thickening. A video-assisted thoracoscopic lung biopsy demonstrated granular eosinophilic material typical of pulmonary alveolar proteinosis.[74] It is unclear if this condition was from the material in the patch or from the fentanyl itself, but it improved after the patient ceased smoking the patches. Multiple case reports of eosinophilic pneumonia have also been reported with the inhalational use of heroin.[53]

The risk of lung cancer among those who smoke or inhale opium or heroin remains unclear.[75] An Iranian study of chronic opium smokers found it to be a significant independent risk factor for developing lung cancer with an odds ratio (OR) of 3.1 (95% confidence interval [CI], 1.2–8.1).[76] When concomitant heavy smoking was combined with chronic opium smoking, the OR increased dramatically to 35.0 (95% CI, 11.4–107.9). A dose-dependent increase in cancer mortality was also seen in opium smokers in Iran.[77] A total of 50,045 adults were enrolled in this study between 2004 and 2008 and followed until 2015 with follow-up rate of 99%. Opium use was determined by questionnaire. The adjusted hazard ratio (HR) for death from a respiratory disease was 3.84 (95% CI, 2.61–5.67). Malignant causes of respiratory deaths were a significant component of these deaths.

Opioid use is associated with some immunosuppression, but the clinical importance has been questioned.[78] Whether due to immunosuppression by the opioids, lifestyle risk, or IV drug use, the rates of tuberculosis among opium users was 5.3% (95% CI, 1.3–10.3), and this rate was higher than among asthma patients or nonsmokers who visited an emergency department for nonrespiratory complaints.[75] Even the use of therapeutic doses of opioids in elderly patients results in an increased risk of pneumonia (OR, 1.38; 95% CI, 1.08–1.76).[79] HIV patients who are also IV drug users are at increased risk for tuberculosis.[80] Separating the roles of lifestyle, IV drug use, and opioids as contributors to this risk is difficult.

MARIJUANA AND SYNTHETIC CANNABINOIDS

Several countries and many states within the United States have relaxed their laws to allow more access to "medicinal" and recreational marijuana.[81] Several comprehensive reviews have been written about the pulmonary effects of marijuana use.[81–84] Although there are some excellent reviews on the chemistry and epidemiology of the more than 50 different synthetic cannabinoids or "spice agents,"[85,86] little is known about the pulmonary complications of their use.[87] Both marijuana/tetrahydrocannabinol (THC) and the synthetic cannabinoids have common psychotropic and acute cognitive effects, but the synthetic cannabinoids demonstrate more agitation and psychosis.[87] Figure 66-3 provides the chemical structure of THC and other cannabinoids. Table 66-4 outlines and summarizes major pulmonary toxicity associated with the use of marijuana and the limited knowledge about the effect of synthetic cannabinoids.

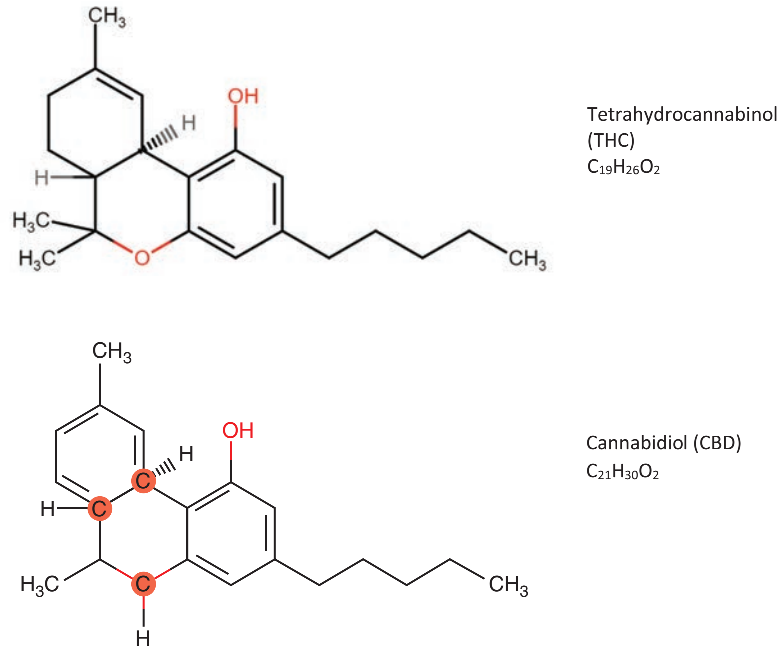

Figure 66-3 Structure of tetrahydrocannabinol (THC) and cannabidiol (CBD).

The combustion of marijuana and the various plant leaves on which synthetic cannabinoids/spice are sprayed gives off both a volatile or gas phase and particulate phase of smoke that are similar to those of tobacco.[81] In contrast to tobacco, which contains nicotine, marijuana contains THC and more than 60 different cannabinoid products. Carbon monoxide, ammonia, hydrocyanic acid, acetaldehyde, isoprene, formaldehyde, acrolein, dimethyl- and methylethyl-nitrosamine, and other polycyclic aromatic hydrocarbons are found in the gas phase of both tobacco and marijuana smoke.[81] The particulate contains phenols and a number of toxic polycyclic aromatic hydrocarbons.

Upper Respiratory Tract/Airway

Unlike tobacco, acute smoking of marijuana can cause bronchodilation probably from the stimulation of cannabinoid airway receptors like CB-1.[82,84,88] The determination of chronic effects of smoking marijuana and synthetic cannabinoids is complicated by the confounder of frequent tobacco smoking in these patients. Both marijuana and synthetic cannabinoids can cause cannabinoid hyperemesis syndrome (CHS) with long-term heavy use.[89–91] This debilitating complication puts patients at risk for aspiration

TABLE 66-4 Recreational Marijuana and Synthetic Cannabinoid Use Pulmonary Toxicity

Toxic Effect
Upper respiratory tract/airway
• Thermal epiglottis
• Asthma exacerbations
• Chronic bronchitis/cough/sputum production
• Possible impaired lung function/chronic obstructive pulmonary disease
Barotrauma/pleural space/extrapulmonary
• Pneumothorax
Pulmonary vasculature
• Pulmonary embolization
Lung parenchyma/alveolar space
• Cannabinoid oil vaping/e-cigarette vaping product use–associated lung injury (EVALI)
• Talcosis with interstitial lung changes
• Noncardiogenic pulmonary edema/acute respiratory distress syndrome (ARDS)
• Pulmonary infections/pneumonia/bronchitis
• Organizing pneumonia
• Pulmonary upper lobe bullae—“pons lung”
• Eosinophilic pneumonia
• Pulmonary hemorrhage
• Possible increased risk for *Aspergillus fumigatus* and *Mycobacterium tuberculosis* in immunocompromised patients including HIV/AIDS
• Possible lung cancer/aerodigestive malignancies

pneumonia. Use of synthetic cannabinoids is also associated with respiratory depression that is rarely seen with the use of marijuana.[92]

Thermal injury resulting in acute epiglottitis has been reported after inhaling or swallowing a lighted marijuana cigarette. In a series of cases of thermal epiglottis from illicit drug use, the majority (3/4) were associated with crack cocaine inhalation and the remaining case with marijuana.[93]

A recent comprehensive review of marijuana smoke exposure concluded that asthmatics should avoid its use in addition to avoiding tobacco smoke.[94] Despite the finding of acute bronchodilation with marijuana smoke inhalation[95] and even after controlling for the use of tobacco, marijuana smokers had more wheezing, cough, sputum production, asthma exacerbations, and emergency department visits for respiratory problems (including asthma exacerbations) than nonsmokers of marijuana.[94] For asthmatics that use marijuana, the overall exacerbation rate is higher, the use of the emergency department is greater, and the asthma treatment adherence and outpatient clinic care use is less than nonusers.[94] Marijuana-related allergies including allergic rhinitis, new-onset asthma, allergic conjunctivitis, eczema, drug eruptions, food allergy, contact urticaria, and anaphylaxis have all been reported with both marijuana inhalation and the ingestion of marijuana in food, teas, and candies.[94] In a systematic review and meta-analysis, increased risk of cough, sputum production, wheezing, and dyspnea was repeatedly seen in adolescents and adult marijuana users compared with nonusers.[96] Heavy use of marijuana by smoking rolled leaves (“joints”) or from a water pipe (“bong”) results in the bronchitis symptoms noted above, and bronchitis pathology has been confirmed by direct airway visualization with airway biopsies showing inflammatory changes.[97,98]

The effects of marijuana smoking on lung function remain controversial in part because of the difficulty of separating out the effects of concurrent tobacco smoking. A cross-sectional study of 2304 current and former tobacco smoking subjects who were also classified as never marijuana smokers, former marijuana smokers, and current marijuana smokers found that marijuana use had little to no association with negative spirometry changes. In fact, increased FEV_1 and forced vital capacity (FVC) numbers were seen in current marijuana smokers. However, higher joint-years (one joint-year equals smoking one joint per day for one year) had more chronic bronchitis symptoms.[99]

A large cross-sectional study of adults in the United States failed to show adverse spirometric lung changes with up to 20 joint-years of marijuana exposure.[100] However, the same study found that patients with greater than 20 joint-years exposure had a twofold increase in odds of having a FEV_1/FVC ratio less than 70%.[100] Interestingly, that was attributed to an increase in FVC rather than the typical decrease in FEV_1 seen among tobacco smokers.[101]

The cross-sectional and longitudinal Canadian Cohort Obstructive Lung Disease (Can COLD) study evaluated older (40–85 years) male and female smokers of tobacco, marijuana, both tobacco and marijuana, and never smokers ($n = 5291$ in the cross-sectional study and 1285 in longitudinal study).[102] When never-smokers were compared with heavy marijuana (>20 joint-years) and heavy tobacco smokers (>20 pack-years), the heavy marijuana or heavy tobacco smokers had a faster decline in FEV_1 by about 29.5 mL/year ($p < 0.0007$) and 21.1 mL/year ($p < 0.0001$), respectively, compared with never-users of either.[102] The greatest decline in FEV_1 of 32.3 mL/year was seen in those who smoked both marijuana and tobacco ($p < 0.0001$). The OR for heavy marijuana users developing COPD was 2.45 (95% CI, 1.55–3.88). These results are limited by the small sample size of the marijuana-only smokers ($n = 181$ in the cross-sectional study and 33 in the longitudinal study).[103] Minimal evidence of obstructive airway disease exists for up to moderate marijuana users, but the effects of heavy use of marijuana are poorly quantitated—in part again because of the frequent confounding by the simultaneous heavy use of tobacco.[81,88,96]

■ Pleural Space/Extrapulmonary Barotrauma

A systematic literature review on pneumothorax and lung emphysema in marijuana/cannabis users included 18 case reports of patients with upper lobe bullae and 8 cases of spontaneous pneumothorax, all in combined tobacco and marijuana smokers.[104] Two additional cases of bullae in the upper lobes were reported in smokers of just marijuana. Further, it was suggested that in patients under age 35 presenting with spontaneous pneumothorax, the incidence of upper lobe bullae was higher in the combined tobacco and marijuana smokers than in the tobacco-only smokers.[104] The mechanism of spontaneous pneumothorax/pneumopericardium and large upper lobe bullae with marijuana smoking is thought to be in part from the mechanical effects of deep breathing and breath holding, Valsalva maneuver during breath hold, and the forcible exhaling of marijuana smoke into another individual’s mouth (“shotgunning”).[81]

■ Pulmonary Vasculature

Limited data exist on whether the use of marijuana or synthetic cannabinoid use can alter the pulmonary vasculature. Two case reports have been published in which the smokers of synthetic cannabinoids developed pulmonary emboli. One case occurred in a 29-year-old and the second in a 32-year-old without any other thromboembolic risk factors noted.[105,106]

■ Lung Parenchyma/Alveolar Space

Inhalation of marijuana and other cannabinoids has been associated with a broad variety of parenchymal abnormalities of the lung. Talcosis with biopsy-proven granulomatous inflammation of the lung and interstitial lung changes on chest CT was reported in a patient who smoked adulterated marijuana.[107] Acute lung injury associated with vaping of THC or cannabidiol (usually with noncommercial products) using an e-cigarette device is called e-cigarette or vaping product use–associated lung injury (EVALI) and is covered in Chapters 41 and 140. Briefly, EVALI appears to be caused by inhalation of oil-based ingredients such as vitamin E acetate in the THC products. It is characterized by bilateral, patchy, mid to upper lobe, ground-glass opacities with subpleural sparing sometimes evolving to diffuse bilateral infiltrates and ARDS requiring mechanical ventilation.[108,109]

Diffuse miliary-micronodular pattern on chest radiography and patchy foci of lower lobe atelectasis and consolidation, with diffuse centrilobular nodules and tree-in-bud pattern on chest CT, has been reported in several patients after inhalation of synthetic cannabinoids.[110] Three out of four patients had lung biopsies that demonstrated organizing pneumonia, with one of the three also showing patchy alveolar damage with eosinophilia. Acute eosinophilic pneumonia associated with respiratory failure was reported in a 21-year-old who smoked synthetic cannabinoids.[111] Acute respiratory failure with diffuse bilateral nodular densities was also seen in two male chronic smokers of synthetic cannabinoids, both of whom ultimately recovered.[112,113]

The concept of "smoking wet" is the process of dipping marijuana in various fluids or lacing it with additional substances.[114] Two cases in which marijuana was tainted by phencyclidine and formaldehyde resulted in acute respiratory failure with ARDS-like infiltrates requiring intubation and extracorporeal membrane oxygenation. Diffuse alveolar hemorrhage (DAH) has been reported after inhalation of both marijuana and synthetic cannabinoids.[115–117] All four DAH patients had acute respiratory failure requiring mechanical ventilation, and negative evaluation for classic causes of DAH. Three of four of the patients were treated with bolus systemic steroids with recovery in all four.

Case reports and case series have reported "bong lung" or large peripheral bullae often associated with pneumothoraces.[118,119] A review of the literature found 57 published cases of bullous lung disease associated with smoking marijuana.[120] It has been postulated that like other forms of barotrauma, these are the results of repeated frequent breath holds and Valsalva maneuvers. A cross-sectional study of 339 subjects divided into nonsmokers, tobacco only, cannabis only, and combined tobacco and cannabis smoking showed reduced lung density on high-resolution lung CT scans in the subjects who smoked cannabis.[121] Microscopic emphysema was seen in 1.3% of cannabis-only smokers, 16.3% of combined cannabis/tobacco smokers, 18.9% of tobacco-alone smokers, and 0% of nonsmokers.

Bronchial biopsies of habitual heavy marijuana users have demonstrated some precancerous histologic changes.[84] A pooled analysis of six case-control studies failed to show an association with smoking marijuana and lung cancer.[84] Two additional studies include a case-control study of 2252 in the Los Angeles area[122] and a smaller case-control trial of 403 subjects in New Zealand.[123] The Los Angeles trial failed to find any correlation with marijuana smoking and lung cancer or oral cancer, while the New Zealand trial found a substantial increased risk for those in the higher marijuana usage group. The Los Angeles study also failed to show an increased risk for oral or pharyngeal cancers with marijuana when adjusting for confounders such as smoking tobacco.[122] A recent systematic review and meta-analysis of 19 case-control, 5 cohort, and 1 cross-sectional studies failed to demonstrate a correlation of marijuana use as measured by joint-years to lung and oral cancers, but the studies had high risk of bias and were not able to be effectively combined.[124]

Marijuana smoking may predispose the user to an increased risk of bronchitis and pneumonia from the loss of ciliated epithelium in the large central airways and hyperplasia of mucous-secreting cells.[84] Several reports of immunocompromised marijuana smokers developing *Aspergillus fumigatus* or *Mycobacterium tuberculosis* infections have been reported.[81] A recent report evaluating the longitudinal Multicenter AIDS Cohort Study found that long-term marijuana smoking was associated with both an increased risk of pulmonary infection and noninfectious pulmonary diseases in patients with HIV.[125] The increased risk of infectious pulmonary diagnoses and of chronic bronchitis with marijuana smoking was independent of tobacco smoking and other known risk factors, with hazard ratios of 1.43 (95% CI, 1.09–1.86) and 1.54 (95% CI, 1.11–2.13), respectively. Shotgunning of marijuana smoke is a potential method of transfer of respiratory pathogens such as tuberculosis.[7] Further prospective and epidemiologic studies are needed to understand infectious disease risks, if any, with extended marijuana use in patients without HIV.

COCAINE-INDUCED PULMONARY TOXICITY

Cocaine has been a common RD over the last 60 to 80 years in the United States, with prevalence of use varying over time and by region. Persons in the United States over age 18 reporting use of cocaine in the past year increased from 2.11% in 2008 to 2009 to 2.26% in 2017, with some states (e.g., California) reporting an increase from 2.2% to 3.04% of the population ($p = 0.002$).[126] Cocaine use appears to be a reemerging public health issue in the United States, with the National Survey of Drug Use and Health (NSDUH) indicating that in 2015, about 968,000 people (0.4% of the population) older than 12 years used cocaine within the last year.[127] In the young adult population between 18 and 25 years old, the U.S. National Survey estimates showed a significant increase ($p \leq 0.05$) in prior-year use from 4.5% (95% CI, 4.22–4.83) in 2013–2014 to 4.98% (95% CI, 4.65–5.34) in 2014–2015.[127] Cocaine overdose deaths also have steadily increased from 4400 in 2012 to 6800 in 2015.[127]

Cocaine hydrochloride or benzoylmethylecgonine (Fig. 66-4) is a naturally occurring alkaloid extracted from the leaf of the plant/shrub *Erythroxylon coca*. When water-soluble cocaine salt is processed via solvent and alkaline extraction, the "freebase" of cocaine is formed. This form has higher volatility and stability and can be smoked. As the crystals or "rocks" of freebase cocaine are heated, it makes a cracking sound leading to the name "crack" cocaine. Cocaine blocks the reuptake of catecholamine in the brain and vasculature, resulting in vasoconstriction. It also has a sodium channel–blocking effect and can act as a local anesthetic. A wide range of respiratory system toxicities are reported with cocaine use (Table 66-5).

A number of contaminants have been found in cocaine sold on the street including phenytoin, local anesthetics, sugars, stimulants, inert compounds, and toxins like strychnine.[128,129] These contaminants have their own toxicities, which will not be discussed here. The combination of cocaine and ethanol generates a unique metabolic product called cocaethylene, which is more potent and likely more toxic than cocaine or its normal metabolites.[130–132] Starting around 2005, the synthetic imidazothiazole derivative levamisole, which has immunomodulatory properties and is a veterinary anthelminthic agent, has been regularly reported as an adulterant in cocaine.[133–136] As a cocaine adulterant, it has been associated with vasculitis, neutropenia, agranulocytosis, skin necrosis, arthralgias, and retiform purpura with or without bullae. Pulmonary complications reported in association with levamisole include pulmonary hemorrhage[133] and the formation of aminorex-like compound

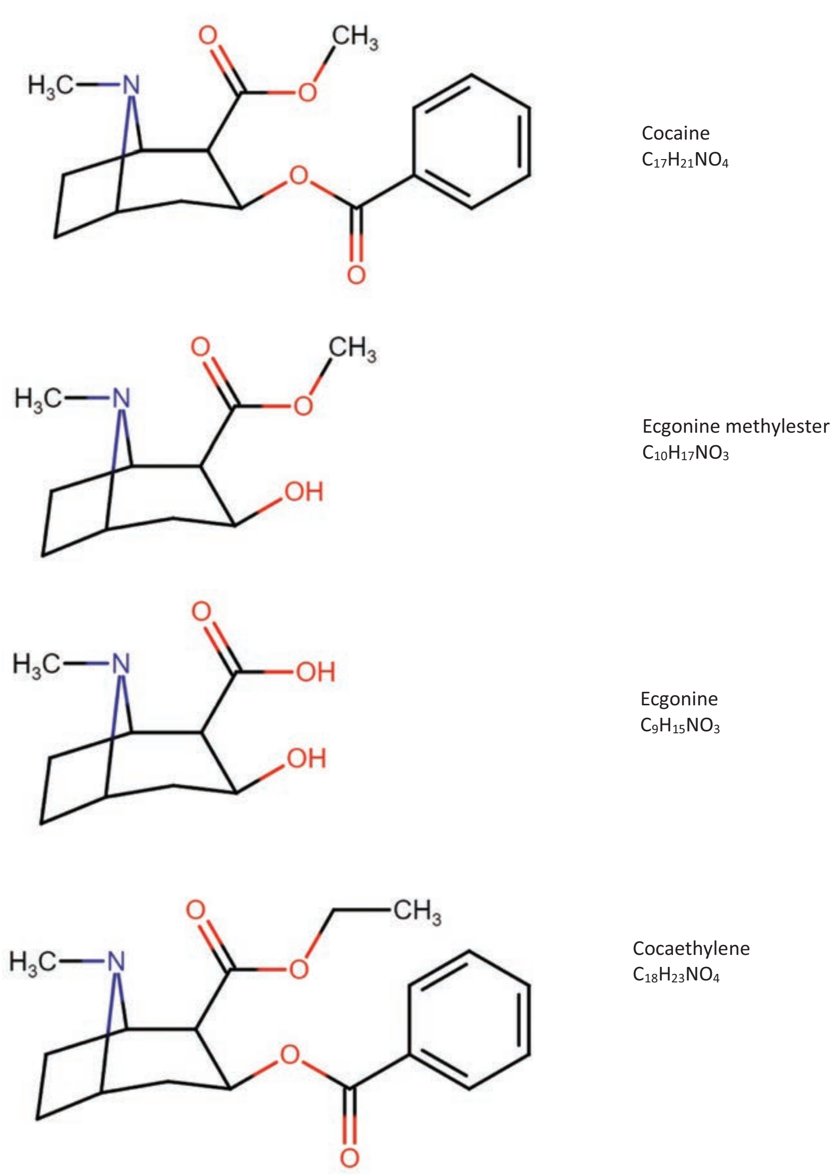

Figure 66-4 Structure of cocaine and metabolites.

metabolites known to cause pulmonary hypertension.[136] Cocaine-induced cardiac affects including myocardial ischemia, cardiogenic pulmonary edema, cardiomyopathy, myocarditis, aortic dissections, endocarditis, and cardiac arrhythmias with sudden death have direct and indirect respiratory system manifestations.[137] Even in animal models with sedation that suppressed most seizure activity, cocaine led to respiratory depression in high doses.[138] Respiratory arrest in human users of cocaine commonly follows seizures, stroke, or cardiac arrest but can also be related to direct central nervous system depression.[139]

■ Upper Respiratory Tract/Airway

The upper respiratory tract is a common site for cocaine toxicity. Snorting or sniffing cocaine deposits large amounts of the drug in the sinuses and cartilaginous areas including the nasal septum. Upper airway necrosis leading to saddle nose deformity and osteolytic sinusitis have been reported.[140–142] Cocaine-induced midline destructive lesions (CIMDL) that mimic granulomatosis with polyangiitis (Wegener granulomatosis) involving the ears, nose, and throat are reported, often in association with positive antineutrophil cytoplasmic antibodies (ANCA).[142–144] Presenting symptoms of CIMDL include nasal/facial pain, nasal obstruction, epistaxis, nasal reflux, and dysphagia. Nasal septal and soft and hard palate perforations can occur with CIMDL.

Upper airway distress from upper airway and tracheal burns is a frequent complication of smoking "crack" cocaine utilizing "crack" pipes or other superheated vaporizing paraphernalia.[145] Stridor, paradoxical vocal cord motion, uvular edema, and necrotic and/or acutely inflamed mucosal tissue are commonly seen. Glass pipes with wire mesh are sometimes used to smoke "crack" cocaine. In one case report, a red-hot wire mesh was aspirated into the pharynx and then swallowed.[146] This caused thermal injury and second-degree burns to the pyriform fossae and the aryepiglottic folds but no injury to the esophagus. There have been several additional cases of inhaled wire-mesh thermal injury to the upper airway from a crack cocaine pipe.[147,148] Severe tracheal thermal damage has also been reported either from an intratracheal ignition of the freebase cocaine ether vehicle or from the resulting housefire.[149]

Both thermal and nonthermal supraglottitis and epiglottitis from cocaine smoking are reported.[93,148,150] Laryngeal aperture narrowing and edema with vocal cord and laryngeal polyps are seen with cocaine smoking[151] and can lead to upper airway obstruction requiring emergent tracheostomy.[151,152] Foreign body aspiration associated with cocaine use is not limited to the previously mentioned pipe components. A freebase cocaine smoker used a 25-gauge hypodermic needle to punch holes in aluminum foil to create a screen for his "crack" pipe, forgot about it, and aspirated the needle into his left upper lobe.[153] Another patient with a long history of nasal cocaine insufflation aspirated a portion of his nasal septum.[154]

Freebase cocaine smoking is associated with exacerbations of asthma and bronchospasm in small case series.[155–157] The largest was a case series of six patients who presented with severe and life-threatening asthma exacerbations after smoking "crack" cocaine.[157] A study of 14 healthy subjects demonstrated that smoking cocaine, but not IV cocaine use, resulted in acute bronchoconstriction thought to be mediated by local airway irritation.[158] Several case reports of freebase cocaine smokers developing obliterative bronchiolitis and bronchiolitis obliterans with organizing pneumonia have been published.[159–163]

Taskin et al. found that compared with age-, sex-, race-, and tobacco/marijuana use–matched non-users, non–freebase cocaine smokers had a mild reduction in DL$_{CO}$, obstructive abnormalities on pulmonary function tests, and respiratory symptoms of cough, black sputum, and chest pain.[162] Although the majority of studies report reduced DL$_{CO}$ among "crack" cocaine smokers, several other studies evaluating DL$_{CO}$ as a measure of the integrity of the alveolar-capillary membrane or interface have failed to show a reduction.[82] Confounders, such as hemoglobin levels, baseline carboxyhemoglobin levels, tobacco and marijuana smoking history, specifics of the cocaine smoking history, and small sample size may explain the variable DL$_{CO}$ results. Smoking "crack" cocaine can produce carbon monoxide, which may confound DL$_{CO}$ determinations. A small study of "crack" cocaine smokers presenting to the ED found that

TABLE 66-5 Recreational Cocaine Use Pulmonary Toxicity

Toxicity
Upper respiratory tract/airway
• Thermal injury
• Foreign body aspiration
• Supraglottitis
• Airway obstruction
• Bronchospasm
• Nasal septum destruction
• Palatal necrosis
• Osteolytic sinusitis
• Asthma exacerbation
• Reduced pulmonary diffusion capacity
Barotrauma/pleural space/extrapulmonary
• Pleural effusions
• Pneumomediastinum
• Pneumothorax
• Pneumopericardium
Pulmonary vasculature
• Pulmonary embolism
• Vasculitis
• Pulmonary hypertension
• Pulmonary infarction
• Foreign body embolism
Lung parenchyma/alveolar space
• Foreign body/cellulose/talc granulomatosis
• Interstitial lung disease
• Alveolar hemorrhage/hemoptysis
• Pulmonary infiltrates
• Increased pulmonary iron concentrations
• Lipoid pneumonia
• "Crack lung"—acute respiratory failure/alveolar hemorrhage/ eosinophilic inflammation
• Pulmonary edema
• Bronchiolitis obliterans organizing pneumonia
• Eosinophilic pneumonia/Loeffler syndrome
• Infections

57% had carboxyhemoglobin levels greater than 4.5%, highlighting the need to measure and control for this variable.[164]

Pleural Space/Extrapulmonary/Barotrauma

Barotrauma leading to subcutaneous emphysema, pneumopericardium, pneumomediastinum, and pneumothorax have been reported among users of cocaine.[82,142,165,166] Forced inspiration with a partner blowing back on a person (back pressure), Valsalva maneuvers, and vigorous inhalation while smoking "crack" cocaine are reported mechanisms for this barotrauma.[167–170] Thermal injuries and adverse vascular effects are reported to be associated with barotrauma.[140,171]

Cocaine-induced pleural and pericardial effusions have been reported in association with negative serologic tests, skin biopsy consistent with leukocytoclastic vasculitis, and renal biopsy revealing proliferative glomerulonephritis.[172] An additional case of pericardial and pleural effusion, without evidence of heart failure or pulmonary emboli, was reported in a "crack" cocaine user.[173]

Pulmonary Vasculature

Evidence of clinically inapparent alveolar hemorrhage has been demonstrated in habitual "crack" cocaine smokers, suggesting chronic damage to the pulmonary microcirculation.[174] The acute use of IV cocaine in chronic habitual "crack" cocaine smokers did not cause short-term increases in pulmonary artery pressures or stroke volume index but did increase the cardiac index.[175]

International classification systems have included cocaine as a possible cause of World Health Organization (WHO) classification 1.3 drug- and toxin-induced pulmonary hypertension.[176] This pulmonary hypertension is thought to result from a direct effect of cocaine on the pulmonary vasculature but also may be related to IV use of cocaine resulting in embolism of talc and cellulose particulate matter in the pulmonary vasculature.[177] A recent study of 88 patients and documented cocaine use with most being "crack" cocaine smokers found systolic pulmonary artery pressures were higher (30.1 ± 13.1 vs. 22.0 ± 9.8 mm Hg; $p < 0.001$) by echocardiogram than those of partially matched controls.[178] The likelihood of having pulmonary hypertension was also increased in the cocaine users (25% vs. 10%; $p = 0.012$). The metabolism of the cocaine adulterant levamisole to aminorex, a known cause of pulmonary hypertension, has been suggested as another potential mechanism for the development of pulmonary hypertension among cocaine users.[179]

Needle and needle fragment embolization into the lungs and heart have been reported in IV cocaine users.[180] A cocaine user "speedballing" (IV injecting the combination of heroin and cocaine) died suddenly and on autopsy was found to have a small-caliber needle protruding into the distal right ventricle with hyperemic myocardium surrounding the needle.[51] Lung sections showed numerous foreign-body type giant cells with polarizable foreign material contributing to presumed pulmonary hypertension from the patient's IV drug use. Media hypertrophy of small- and medium-sized pulmonary arteries without evidence of foreign body microembolization has also been reported in cocaine users.[82] Septic embolism from right-sided endocarditis can be seen in IV cocaine users.[5] Pulmonary infarctions have also been linked to cocaine use.[181]

Lung Parenchyma/Alveolar Space

Cocaine is one of many drugs that can cause lung parenchymal changes.[182] The term "crack lung" defines a syndrome that is seen between 1 and 48 h after heavy smoking of cocaine and manifests as fever, hypoxemia, hemoptysis, diffuse alveolar infiltrates without pleural effusions, pulmonary and peripheral eosinophils, and IgE deposition within the lung.[142,183,184] Removing the cause by stopping the use of "crack" cocaine is clearly indicated, but it is unclear whether supportive care alone or supportive care plus immunosuppressive agents like corticosteroids is the optimal treatment. A series of three patients in the United Kingdom developed "crack lung" after smoking cocaine prepared with ammonia.[185] One unconscious patient had the diagnosis of "crack lung" aided by the presence of bilateral thermal burns and later confirmed by history.[186]

Diffuse pulmonary hemorrhage outside of the complete "crack lung" syndrome also has been reported.[159,187–189] Diffuse pulmonary hemorrhage has been observed after the use of cocaine hydrochloride by the nasal route.[190] The pulmonary hemorrhage associated with cocaine smoking can result in massive hemoptysis.[191] Subclinical hemorrhage appears to be relatively common, as suggested by a study of volunteers including nonsmokers, "crack" cocaine smokers, "crack" cocaine and tobacco smokers, and smokers of tobacco alone who underwent bronchoalveolar lavage.[192]

Macrophages from cocaine or cocaine and tobacco smokers had elevated iron and ferritin levels compared with nonsmokers or tobacco-only smokers.

As noted previously, chronic damage to the pulmonary microcirculation occurs in "crack" cocaine smokers;[174] pulmonary hemorrhage associated with anti–glomerular basement membrane antibody-mediated glomerulonephritis also has been noted.[193] A spectrum of cocaine-induced vasculitis has been described, some with positive ANCA and some without.[194] The cocaine additive levamisole has been associated with the development of a positive ANCA and Wegener-like granulomatosis with chronic sinus disease, hemoptysis, skin abnormalities, and glomerulonephritis.[195–197] A case of cocaine-induced eosinophilic granulomatosis with polyangiitis (Churg-Strauss vasculitis) with pulmonary infiltrates and skin/muscle biopsies demonstrating eosinophilic angiitis has been reported.[198] Another cocaine smoker was reported to develop rhabdomyolysis and hemoptysis that mimicked a pulmonary embolism.[199] Other cocaine-associated reports of parenchymal lung abnormalities include a "crack" cocaine–induced syndrome that mimicked sarcoidosis, as well as talc foreign body and cellulose granulomas in cocaine sniffers,[200–202] and cocaine-induced eosinophilic lung diseases/Loeffler syndrome.[203–205] In a case of progressive chronic interstitial pneumonitis associated with "crack" cocaine abuse, a lung biopsy revealed histiocytes with extensive accumulation of silica.[206]

Although cocaine-associated pulmonary edema is noted on autopsy of patients who have died of cocaine overdoses,[207] an early report of a series of five acutely ill patients demonstrated what was thought to be noncardiogenic pulmonary edema.[208] Several other case reports have reported presumed noncardiogenic pulmonary edema after smoking or using cocaine IV.[209,210] Pulmonary edema in an infant following passive freebase "crack" cocaine smoke exposure also has been reported.[211] Postoperative pulmonary edema occurred in a cocaine addict despite reportedly not having used cocaine for 2 weeks.[212] Reactive oxygen species as the result of norcocaine and subsequent redox cycling between the N-hydroxy metabolite and a nitroxide radical of cocaine are postulated as one cause of pulmonary edema and interstitial lung disease with cocaine.[213] Two cocaine users who developed a "flu-like" syndrome after using cocaine and presented with interstitial lung damage had allelic variants for a vitamin K epoxide reductase complex and CYP2C9/CYP2C19.[214]

In addition to noncardiogenic pulmonary edema and other interstitial lung changes with cocaine, alveolar accumulation of carbonaceous material on bronchoalveolar lavage in a cocaine smoker with pulmonary infiltrates was reported.[215] A retrospective study of bronchoalveolar fluid or sputum in 14 hospitalized patients with a history of heavy cocaine smoking found carbonaceous sediment similar to heavy tobacco smokers but, unlike in tobacco use, in the cytoplasm of alveolar macrophages.[216] One of the hallmarks of "crack" cocaine smokers is the production of carbonaceous sputum.

Other parenchymal injuries include the case of patient with bronchiolitis obliterans organizing pneumonia thought to be associated with heavy freebase cocaine smoking.[217] Pulmonary embolism with infarction was also reported in a healthy young cocaine smoker without pre-existing disease or distal source.[218] A case of exogenous lipoid pneumonia was reported from a smoker of cocaine who mixed his freebase cocaine with petroleum jelly to make the drug last longer.[219] The obvious limitation of these case reports and few case series is that the association of these pathologic processes with cocaine use does not establish causality.

Little evidence exists, though, of an increased risk for chronic bronchitis, and only a slight increased risk of pneumonia was seen in cocaine users between 35 and 49 years of age in the United States between 2005 and 2007 in the National Surveys on Drug Use and Health.[220] In contrast, data from London using a case-control study approach found a relative risk of 2.4 (95% CI, 2.0–2.9; $p < 0.001$) for smear-positive tuberculosis compared with non-drug users.[221] A case of botulism from a *Clostridium botulinum* sinusitis was reported in a 25-year-old male who had used intranasal cocaine.[222] His initial bulbar paralysis became complete flaccid quadriplegia that required 6 months of mechanical ventilator support before a gradual recovery.

HUFFING/VOLATILE SUBSTANCE MISUSE

The use of volatile substances to induce intoxication ("huffing") is inexpensive and popular among teens but used by all ages.[223] Aerosol paints, adhesives, glues, air fresheners (butane or isobutene), gas fuels, and computer dusters containing 1,1-difluorothane are the volatile substances (VS) most abused.[223] The U.S. National Electronic Injury Surveillance System has reported a fivefold increase in duster spray inhalation–related injuries between 2008 and 2016.[224] VS toxicity is mainly neurologic, cardiac, and dermatologic, but the respiratory tract also may be affected. Rapid airway compromise from upper airway frostbite following recreational use of "huffed" air duster has been reported.[225] Orofacial and digital frostbite from VS abuse using aerosolized computer cleaner containing the fluorocarbon HFC-134a resulted in a loss of consciousness but no requirement for intubation.[226]

Volatile substance misuse (VSM) involves a variety of compounds that can cause a variety of pulmonary injuries. An outbreak of pulmonary toxicity occurred following a change in formulation of a commercial leather conditioner, with complaints of cough, chest pain, and shortness of breath.[224] A case of pneumomediastinum and pneumopericardium along with subcutaneous emphysema was reported after a 32-year-old man inhaled 6 to 10 cans of a computer cleaning product containing 1-1-difluoroethane.[227] An 18-year-old male who sniffed keyboard cleaner developed pneumonia, diffuse alveolar hemorrhage, and hemoptysis culminating in death.[228] Using technetium-99m DTPA aerosol to study alveolar-capillary permeability has shown that glue-sniffers and other VS abusers have abnormalities in pulmonary alveolar-capillary membrane function.[229] A case-control study compared 31 males with an average age of 14.6 years (9–18) at the onset of VSM to 19 control subjects.[230] The VS abusers had complaints of nasal congestion (45.2%), sputum production (38.7%), exercise intolerance (32.3%), and cough (22.6%). A reduction in FVC consistent with a restrictive pattern was noted on spirometry, and these changes seemed to correlate with abnormalities on HRCT.[230] Sudden death with pulmonary edema has been reported as a result of VSM using glue and gasoline.[231,232] Anti–glomerular basement membrane (GBM) disease (Goodpasture syndrome), an autoimmune disease that is characterized by glomerulonephritis, diffuse alveolar hemorrhage, and anti-GBM antibodies has been linked in part to hydrocarbon exposure.[233] A review of all reported cases of anti-GBM disease and hydrocarbon exposure determined that such cases accounted for 6% of all reported cases and found no disease features or predictors of outcome associated with type or duration of hydrocarbon exposure.[233] The 2005–2007 National Surveys on Drug Use and Health for bronchitis with relationship to inhalant exposures of ≤1 year, 2 to 10 years, and ≥11 years in duration found that compared with "never-users," the OR for development of bronchitis was 1.54 (95% CI, 1.30–1.82), 1.51 (95% CI, 1.21–1.89), and 1.46 (95% CI, 0.92–2.26), respectively. The same exposure categories for pneumonia found an OR of 1.52 (95% CI, 1.22–1.90), 1.68 (95% CI, 1.26–2.24), and 1.57 (95% CI, 0.98–2.50), respectively.[220] Although the literature is not as deep for pulmonary toxicity with VSM as with the other RDs reviewed, it still suggests a significant respiratory risk.

CONCLUSION

Use and abuse of RDs are associated with a variety of abnormalities of the respiratory system, ranging from upper airway injury to infectious and noninfectious disorders of the pulmonary vasculature and lung parenchyma. Patterns of involvement vary by drug and route of administration. Some respiratory manifestations are related to mechanisms of administration (embolization of needle fragments or pneumothorax due to supraclavicular drug injection) and adulterants, rather than due to the RDs themselves. RD use that includes sniffing, inhaling, IV injecting, or burning and smoking agents appear to be associated with significant pulmonary risks. Familiarity with the various direct and indirect respiratory system manifestations of RD use and abuse is crucial for the practicing pulmonary physician.

CHAPTER 67

The Lungs in Patients with Inborn Errors of Metabolism

Timothy Craig Allen

INTRODUCTION

A variety of inherited systemic conditions cause different types of disease-producing chemical imbalances affecting essentially all organs to some degree; these conditions are called *inborn errors of metabolism* and also are termed *inherited metabolic disorders.*[1–16] Each is characterized by a specific genetic defect resulting in an abnormality of an enzyme necessary for the degradation of a chemical substance.[2,6] The disruption of the chemical constituent's degradation results in disease by causing either a deficiency of a substance or a pathologic accumulation of a substance.[1,2,6,9] The first of these disorders was identified by Sir Archibald Garrod, who coined the term *inborn errors of metabolism* in 1902.[14] There are currently more than 600 inborn errors of metabolism that have been discovered.[2,15]

Each specific inborn error of metabolism is rare, but overall, approximately 1 in 1000 people are affected.[1,2,6] Most show autosomal recessive inheritance; however, X-linked recessive inheritance occurs, and, less commonly, autosomal dominant inheritance.[9] Most of these diseases arise in children; however, with the identification of attenuated variants, and with continuing improved survival, some of the conditions must be considered in any-age patients.[1,2,6]

Inborn errors of metabolism often present with unexpected findings and lead to a high clinical suspicion. Fast and accurate radiologic diagnosis and clinical–radiologic correlation are critical for successful therapy because newer and more effective approaches are being designed and require early diagnosis.[2,6] While specialists with expertise in various inborn errors of metabolism are found in academic institutions, primary care physicians and pediatricians are frequently the first physicians to encounter these patients.[9]

Some conditions fall into a few broad groups, including disorders of amino acid metabolism, organic acidurias, urea cycle defects, disorders of ketogenesis and ketolysis, disorders of fatty acid oxidation, lysosomal storage disorders, and mitochondrial disease.[2,6] The lung is rarely a primary site of clinical disease in these patients; however, pulmonary involvement occurs in many of the disorders, resulting in clinically significant lung disease in some.[2,5,16] Pulmonary infections are not an uncommon secondary feature in many inborn errors of metabolism. This chapter highlights some specific inborn errors of metabolism in which lung disease may be a clinically significant feature.

ACID SPHINGOMYELINASE DEFICIENCY (NIEMANN-PICK DISEASE TYPES A AND B)

An autosomal recessive condition, acid sphingomyelinase (ASM) deficiency, has a phenotype that occurs in a continuum. Niemann-Pick disease type A (NPA) shows severe, neuropathic disease with early symptoms, resulting in death in infancy or early childhood. Niemann-Pick disease type B (NPB) shows nonneuropathic disease with generally later onset and milder symptoms.[1–4,17–25] Patients with NPA typically develop hepatosplenomegaly by approximately 3 months of age. Hepatosplenomegaly may become massive and is often fatal within 3 years. Psychomotor development usually takes place within 2 months, after which patients deteriorate. NPB patients typically exhibit milder hepatosplenomegaly, and patients may survive to adulthood. These patients often have progressive, clinically significant pulmonary alterations.[22,26,27] Diagnosis is confirmed by demonstration of <10% normal residual acid sphingomyelinase activity in peripheral blood lymphocytes or cultured skin fibroblasts.

NPA causes radiographic changes of interstitial lung disease due to sphingomyelin storage[30] within pulmonary macrophages. Patients with NPA often have low arterial blood oxygen levels. They experience frequent respiratory infections that may culminate in respiratory failure and death.[17,20,21,29,30] Patients with NPB may develop pulmonary complications at any age.[29,30] Radiographic changes of interstitial lung disease occur even though each individual patient's symptoms may vary dramatically. Further, the radiographic changes usually do not correlate with the severity of their pulmonary function alterations.[20,22,26] Cystic lung disease may be seen in patients with NPB.[31] Whole lung lavage has been attempted for symptomatic treatment.[32] Pulmonary fibrosis occurs over time.

Radiographically, patients with MPB exhibit nodular infiltrates and linear strands, with predominantly basilar honeycombing.[27,33] Histologically, there is predominantly normal interstitial architecture, with airspaces filled with Niemann-Pick cells, which are enlarged histiocytes with finely vacuolated cytoplasm[34] (Figs. 67-1 and 67-2). CD68 immunostain highlights these cells and may assist in establishing their presence. Pathologists have termed these collections of cells *sea blue histiocytosis* because of their vivid blue staining with May-Grunwald Giemsa stain. Pulmonary fibrosis may occur over time (Fig. 67-3).

NIEMANN-PICK DISEASE TYPE C

A rare, autosomal recessive inborn error of metabolism, Niemann-Pick disease type C (NPC) is characterized by impaired intracellular lipid trafficking and accumulation of cholesterol and glycosphingolipids in the brain and other organs.[35–42] Diagnosis is rendered via biochemical testing showing impaired cholesterol esterification and positive filipin staining in cultured fibroblasts.

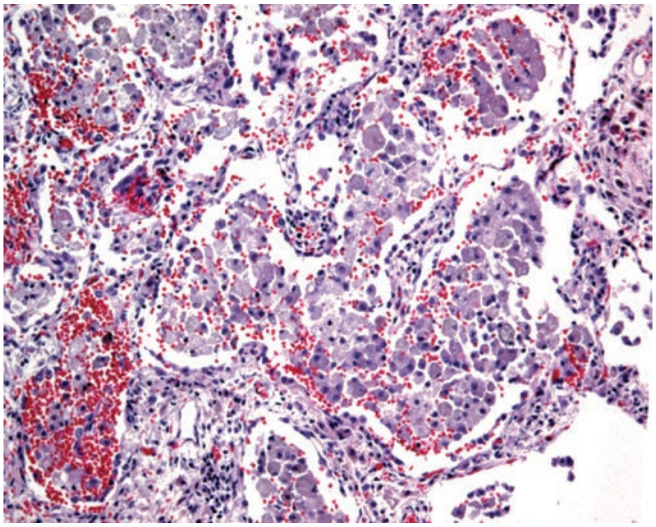

Figure 67-1 Low-power image of lung in Niemann-Pick disease showing collections of foam cells within alveoli.

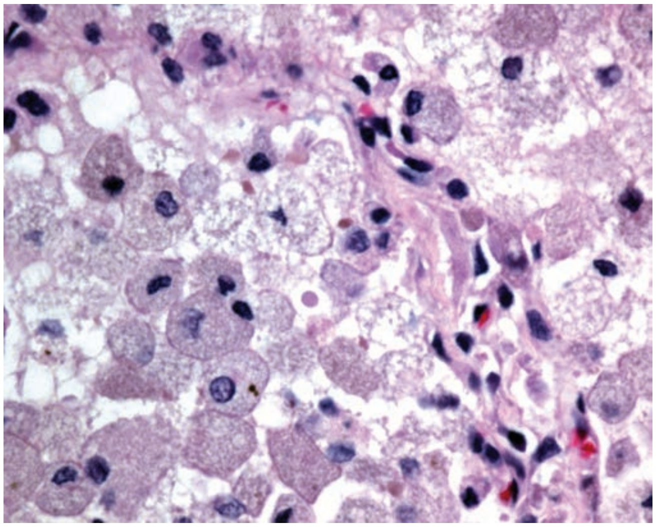

Figure 67-2 High-power image of lung in Niemann-Pick disease showing enlarged histiocytes with finely vacuolated cytoplasm within the alveolar spaces.

Patients exhibit saccadic eye movement abnormalities or vertical supranuclear gaze palsy; cerebellar signs include ataxia, dystonia/dysmetria, dysarthria and dysphagia, gelastic cataplexy, and epileptic seizures.[35,41] Cataplexy, dystonia, and seizures are treated symptomatically, and physical therapy is used to maintain independent mobility. Approximately 95% of cases of NPC are due to mutations of the *NPC1* gene, and the remainder are due to mutations of the *NPC2* gene.[35]

NPC may produce symptoms in patients of any age, and the initial presentation may occur from neonate to adult. Infants usually display nonspecific symptoms, making a definitive diagnosis difficult. In addition to liver disease, infants may present with often-fatal pulmonary failure caused by impaired gas exchange secondary to infiltration of the lungs with foam cells. Patients presenting in childhood, adolescence, or adulthood usually do not have pronounced pulmonary involvement.[38–40,45] These patients may develop pulmonary alveolar proteinosis, perhaps secondary to the loss of normal NPC2 protein expression in alveolar macrophages and accumulation of functionally inactive cholesterol-rich surfactant.[41,42,44]

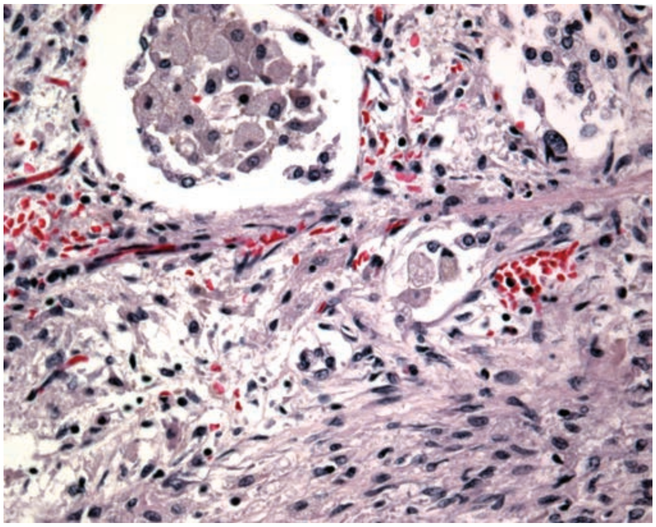

Figure 67-3 High-power image of lung in long-standing Niemann-Pick disease showing developing pulmonary fibrosis.

Bronchoalveolar lavage reportedly improves pulmonary symptoms in children with foam cell infiltrates. Pathologic features on biopsy are similar to those seen with patients with NPA and NPB.

GAUCHER DISEASE

An autosomal recessive disease, Gaucher disease (GD) is due to inadequate lysosomal enzyme glucosylceramidase activity, resulting in the accumulation of glucosylceramide, the enzyme's undegraded substrate, and other glycolipids.[1–4,16,46–49] The undegraded substrate arises primarily from the breakdown of red blood cells and other tissue cells and is then engulfed by monocytes and macrophages. Central nervous system involvement with GD may be due to membrane ganglioside turnover; however, neuron death also may be causative.[50]

GD consists of three main clinical subtypes and two additional subtypes, each with its own characteristic features. Types 1, 2, and 3 GD often exhibit lung involvement. Type 1 GD is clinically characterized by bone disease, particularly osteonecrosis, lytic and sclerotic, lesions, and osteopenia. Anemia, thrombocytopenia, and hepatosplenomegaly also occur. These patients usually do not exhibit central nervous system involvement.

Type 2 and type 3 GD are both characterized by central nervous system involvement with disease. Patients with type 2 GD usually present with disease before age 2 years and exhibit poor psychomotor development. They rapidly deteriorate and usually die between ages 2 and 4 years. In contrast, patients with Type 3 GD usually present before age 2 years; however, these patients slowly progress, and some survive to adulthood. There are also 2 additional subtypes of GD, in which pulmonary involvement is not characteristic. Cardiovascular GD exhibits mitral value and aortic valve calcification, corneal opacities, and supranuclear ophthalmoplegia. Perinatal lethal GD shows nonimmune hydrops fetalis or skin abnormalities.

GD may be caused by mutations in saposin C and acid-β-glucosidase.[51] Diagnosis requires the demonstration of inadequate glucosylceramidase activity in peripheral blood leukocytes or other cells. Treatments for these patients include enzyme replacement therapy and substrate reduction therapy.[52–55]

Pulmonary involvement in patients with GD involves pulmonary hypertension, lobar consolidation, and interstitial lung disease.[1,2,5,16,47,56,57] Pulmonary hypertension is a frequent finding in patients who have hepatic disease, possibly due to patients' inability to detoxify gut-derived factors that affect the pulmonary endothelium, with resultant pulmonary hypertension. However, it may also arise in patients without liver diseases.[56] Some patients with type 1 GD without pulmonary disease may, nonetheless, exhibit rapid fatigability, probably due to GD-induced circulatory impairment.[4,16,57,58]

Histologically, GD cells infiltrate the liver, spleen, and bone marrow. Lung involvement with GC cells is common in pediatric patients but not in adults.[59] Lung involvement with GC cells may cause clinical sequelae in up to one-third of patients.[60] GD cells usually involve septal capillaries, constituting the likely the cause of GD-associated pulmonary hypertension.[60] Intra-alveolar involvement with GD cells may be seen in infants and children and has been found to cause substantial septal thickening and patchy involvement in a lymphatic distribution.[60] The Gaucher cell has a characteristic "wrinkled paper" appearance (Fig. 67-4), and these cells are highlighted with periodic acid–Schiff (PAS) staining. Gaucher cells are CD68 negative, in contrast to alveolar macrophages, which display CD68 positivity.[61]

FABRY DISEASE

Fabry disease (FD) is an X-linked lysosomal storage disease caused by a deficiency of α-galactosidase A enzyme activity. The deficiency causes globotriaosylceramide accumulation in several tissues, including cardiomyocytes, smooth muscle cells, and endothelial

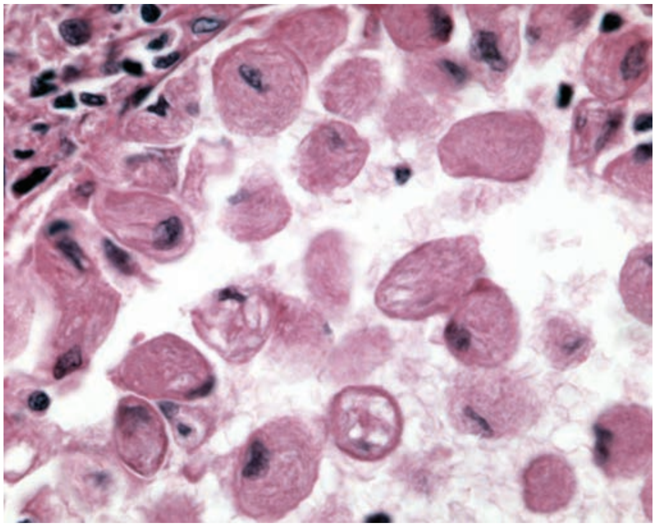

Figure 67-4 High-power image of Gaucher cells within an alveolar space showing the characteristic "wrinkled paper" appearance.

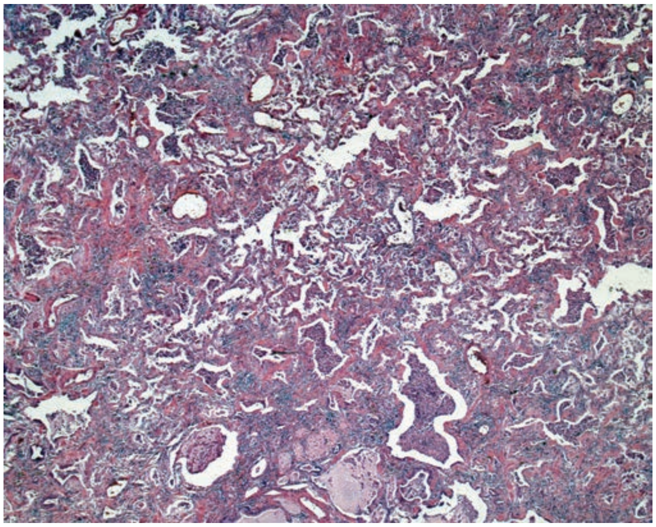

Figure 67-5 Medium-power image of lung in Hermansky-Pudlak syndrome showing a nonspecific interstitial pneumonia–like pattern.

cells.[1,2,4,62–65] Males with less than 1% enzyme activity develop the classic form of FD, which usually arises in childhood or adolescence and is characterized by proteinuria, corneal and lenticular opacities, angiokeratomas, hypohidrosis, and periodic episodes of markedly painful extremities. Gradually worsening renal disease leads to end-stage renal disease by the third to fifth decade of life. If these patients do not succumb to renal disease, they usually die of their cerebrovascular or cardiovascular disease.

Men with greater than 1% enzyme activity usually either exhibit a renal variant resulting in end-stage renal disease, but without extremity pain or skin lesions, or they exhibit a cardiac variant, often in their sixth to eighth decade, with proteinuria, mitral value insufficiency, cardiomyopathy, and left ventricular hypertrophy, but without end-stage renal disease. Women with FD, heterozygous for the disease, typically show later disease onset and milder symptoms than men. They may be asymptomatic throughout life or have mild symptoms mimicking men with classic FD. The diagnosis in men is made by displaying α-galactosidase A enzyme deficiency in leukocytes, cultured cells, or plasma. Enzyme measurement is not a reliable test for women, as some carriers have decreased enzyme activity, while others show normal activity. Enzyme testing for a mutation in *GLA*, the gene associated with FD, is necessary for diagnosis in women carriers. Men essentially always show a *GLA* mutation. Male patients with FD and symptomatic women carriers can be treated with enzyme replacement therapy.[58,62–64]

Both women and men may have pulmonary involvement with FD.[2,4,16,66–68] Patients with FD often exhibit dyspnea, wheezing, and chronic bronchitis; pulmonary function tests may show obstruction. Radiologic changes may be minimal and are not associated with the severity of pulmonary function. Histologic diagnosis of FD is made by identification of laminated inclusions in type II pneumocytes and capillary endothelium.[68] Lamellar inclusions reportedly have been identified in alveolar macrophages, ciliated epithelial cells, and goblet cells cytologically in induced sputum samples, brushings, and bronchoalveolar lavage specimens.[68–71]

HERMANSKY-PUDLAK SYNDROME

A rare, autosomal recessive, multisystem disease, Hermansky-Pudlak syndrome (HPS), also termed *oculocutaneous albinism syndrome*, involves intercellular trafficking and is characterized by tyrosinase-positive oculocutaneous albinism, a platelet storage pool deficiency that causes bleeding diatheses, and sometimes, pulmonary fibrosis.[4,72–84] Patients with HPS display congenital nystagmus, decreased visual acuity, iris transillumination, and variable skin and hair hypopigmentation. Approximately 15% may also develop granulomatous colitis.[76–78,85,86]

HPS is diagnosed clinically, and the ultrastructural absence of platelet dense bodies may be used as a confirmatory test. Patients with HPS usually exhibit easy bruising and prolonged bleeding. HPS is caused by mutations in several genes and causes several HPS subtypes, including *HPS1*, causing HPS-1; *AP3B1*, causing HPS-2, *HPS3*, causing HPS-3; *HPS4*, causing HPS-4; *HPS5*, causing HPS-5; *HPS6*, causing HPS-6; *DTNBP1*, causing HPS-7; *BLOC1S3*, causing HPS-8; and *BLOC1S*, causing HPS-9.[78,79,88]

Pulmonary involvement in patients with HPS often presents clinically and radiologically as pulmonary fibrosis. It is usually symptomatic by the fourth decade. The disease is progressive and causes restrictive lung changes, and it may cause death within a few years of pulmonary symptom onset. Pulmonary fibrosis is often identified in patients with HPS-1, HPS-2, and HPS-4; it is particularly prevalent in patients with HPS-1 from Puerto Rico.[77,85,89–96] Pulmonary fibrosis is not characteristically present in patients with HPS-3, HPS-5, or HPS-6 disease. Lung transplantation may be appropriate for some patients.[97] The cause of the pulmonary fibrosis is unknown; however, it has been hypothesized that a postinflammatory response is the causative factor.[98] Treatment with pirfenidone has been attempted in patients with pulmonary function greater than 50% of normal, with some reported benefit.[90]

Histologically, the pulmonary fibrosis may show a pattern of usual interstitial pneumonia or nonspecific interstitial pneumonia.[85,98] Ceroid-filled macrophages fill airspaces and the lung interstitium (Figs. 67-5, 67-6, and 67-7) and may be identified with bronchoalveolar lavage.[99]

CHOLESTERYL ESTER STORAGE DISEASE

Cholesteryl ester storage disease (CESD) is a rare autosomal recessive disease characterized by lysosomal acid lipase/cholesteryl ester hydrolase deficiency. Patients with CESD have some enzyme activity, and patients with complete enzyme deficiency are properly diagnosed as having Wolman disease.[101–103] In patients with CESD, there is deposition of cholesteryl ester in the liver, as well as in the bone marrow, gastrointestinal tract, and spleen. Gastrointestinal bleeding, often occult, and hepatomegaly are frequently identified.[103] Patients usually survive into adulthood, ultimately succumbing to chronic hepatic failure or premature atherosclerosis.[101]

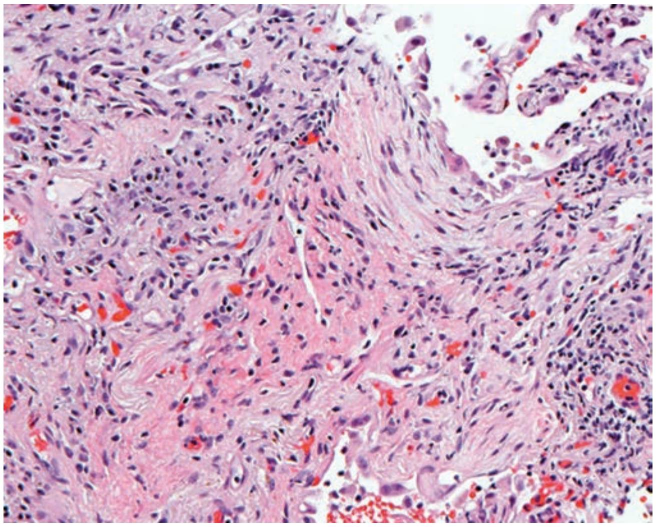

Figure 67-6 Higher-power image of lung in Hermansky-Pudlak syndrome showing a usual interstitial pneumonia–like pattern.

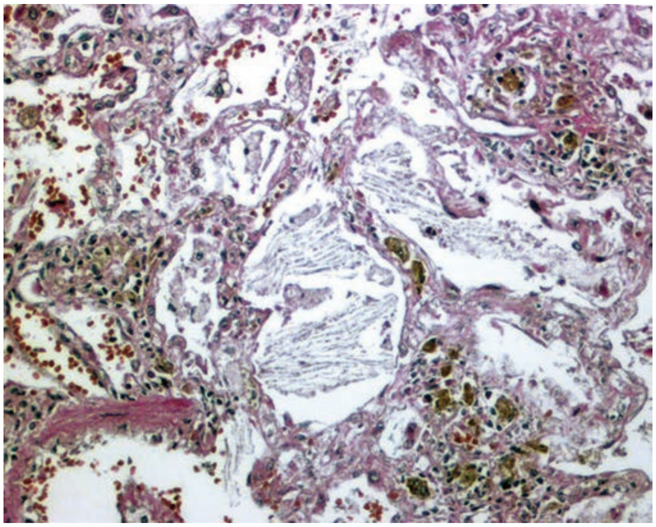

Figure 67-8 Medium-power image of lung in cholesteryl ester storage disease showing cholesteryl ester accumulation within alveolar macrophages, and interstitial fibroblasts.

Pulmonary involvement with CESD is uncommon but may occur secondary to the accumulation of cholesteryl esters in alveolar macrophages and interstitial fibroblasts **(Figs. 67-8 and 67-9)**. The pulmonary arteries can also develop intimal foam cell deposits, often complicated by associated reactive fibrosis.[104,105] Treatment of pulmonary disease is supportive; however, for most patients, pulmonary involvement is not life-threatening.[104]

MUCOPOLYSACCHARIDOSIS TYPE I

Mucopolysaccharidosis type I (MPS1), an autosomal recessive disease, is a progressive multisystem lysosomal storage disorder caused by deficiency of the enzyme α-L-iduronidase.[106,107] Patients with MPS1 vary in disease severity. Patients with Hurler syndrome, Hurler-Scheie syndrome, and Scheie syndrome show overlapping clinical features and no biochemical differences and currently are diagnosed clinically with either severe MPS1 (formerly, Hurler syndrome) or attenuated MPS1 (formerly, Hurler-Scheie Syndrome and Scheie Syndrome). MPS1 is diagnosed by demonstration of insufficient α-L-iduronidase activity in plasma, cultured fibroblasts, or peripheral blood leukocytes. Treatments include enzyme replacement therapy and bone marrow transplantation.[106–109] Attenuated patients with MPS1 may have pulmonary disease and demonstrate changes in forced vital capacity. In patients with pulmonary disease, respiratory complications are usually the cause of death.[110]

MUCOPOLYSACCHARIDOSIS TYPE II

Mucopolysaccharidosis type II (MPSII), also termed *Hunter syndrome*, is inherited as an X-linked recessive multisystem disease and is characterized by the pathologic lysosomal storage of glycosaminoglycans.[111–113] Most patients are men; carrier women rarely display clinical features.

Patients with MPSII usually have central nervous system involvement, with progressive deterioration of cognitive function. These patients usually have macrocephaly, with or without communicating hydrocephalus, hoarseness, hearing loss, macroglossia, splenomegaly, hepatomegaly, short stature, dysostosis multiplex, and joint contractures.[112,113] Severe cases have had cardiac disease and progressive airway disease and often died before or within their second

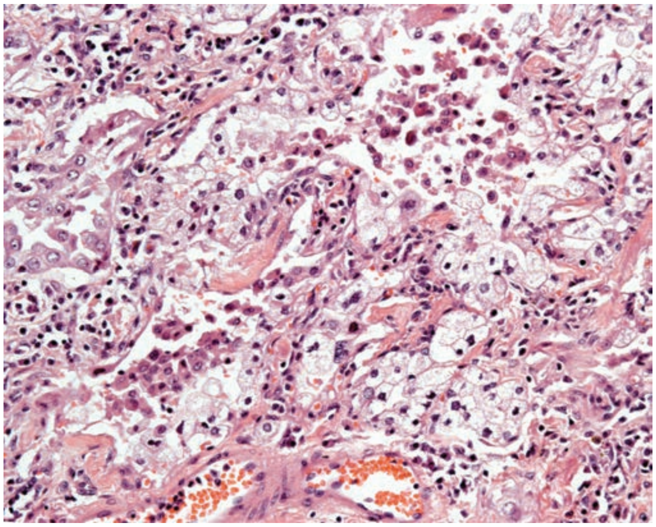

Figure 67-7 High-power image of lung in Hermansky-Pudlak syndrome showing ceroid-filled histiocytes within alveolar spaces.

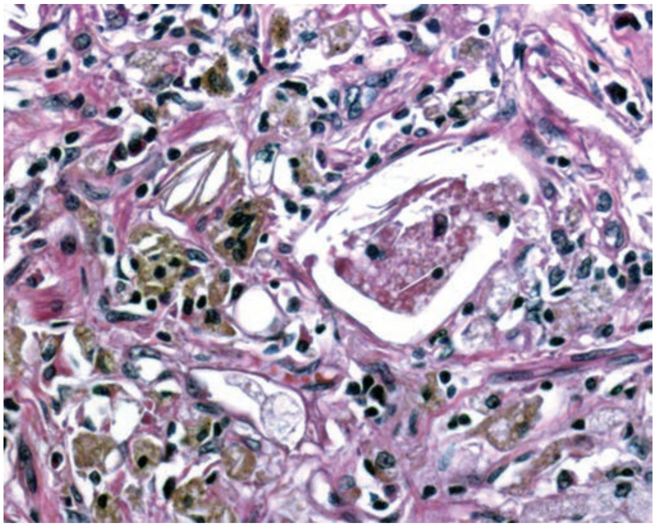

Figure 67-9 High-power image of lung in cholesteryl ester storage disease showing alveolar macrophages containing cholesteryl esters.

decade of life. Disease severity is on a continuum, and clinical manifestations and progression can vary significantly. Some patients with milder forms of disease display normal intelligence into early adulthood and survival into the sixth decade.[112,113]

Testing for deficient iduronate sulfatase enzyme activity in plasma, fibroblasts, or white blood cells may be performed, and diagnosis may be confirmed by molecular testing of *IDS*, the gene associated with MPSII. Treatment has traditionally been supportive.[111] Bone marrow transplantation has been unsuccessfully attempted.[114] Enzyme replacement therapy is being studied.[112,115–118]

Patients with MPSII frequently develop frequent upper respiratory infections early, with progressive airway narrowing due to severe airway obstruction caused by the accumulation of glycosaminoglycans in the tongue, upper airway, and trachea.[111,113] Progressive airway obstruction with associated sleep apnea may require tracheostomy. Airway obstruction, along with hepatomegaly and splenomegaly, thick pulmonary secretions, and chest wall stiffness may reduce lung volumes.[112]

CHAPTER 68

Alveolar Hemorrhage Syndromes

Joseph P. Lynch, III
Michael C. Fishbein
Tisha S. Wang

INTRODUCTION

Diffuse alveolar hemorrhage (DAH) is a potentially catastrophic complication of myriad immune and nonimmune disorders.[1–3] Clinical features are broad, but hemoptysis, infiltrates on chest imaging, hypoxemia, and progressive respiratory insufficiency are commonly seen in many other diverse etiologies.[3] Other causes of diffuse parenchymal infiltrates (e.g., cryptogenic organizing pneumonia, hypersensitivity pneumonia, pulmonary alveolar proteinosis, other interstitial or alveolar lung disorders) must be excluded. Additionally, *nonimmune causes* of pulmonary alveolar hemorrhage include endobronchial tumors, arteriovenous malformations or aneurysms, ulcerative tracheobronchitis, hemorrhagic pneumonia, bronchiectasis, congestive heart failure, uremia, thrombocytopenia or coagulopathy, pulmonary veno-occlusive disease, massive pulmonary embolism, and infections.[4,5] Depending upon the clinical scenario, coagulation profiles and ancillary tests (e.g., echocardiogram, chest computed tomographic [CT] pulmonary angiography, bronchoscopy) may be required to establish a specific diagnosis. A discussion of these disorders is beyond the scope of this chapter, which focuses primarily on *immune-mediated* causes of DAH. We begin with an overview of the many syndromes causing alveolar hemorrhage before discussing each individually.

AUTOIMMUNE CAUSES OF ALVEOLAR HEMORRHAGE: DIFFERENTIAL DIAGNOSIS

Autoimmune DAH results from diffuse injury to the pulmonary microvasculature (termed *capillaritis* or *endotheliitis*) (Table 68-1).[2,6] Systemic necrotizing vasculitides[1,7–10] (principally, microscopic polyangiitis [MPA][11–15] and granulomatosis with polyangiitis [GPA, formerly Wegener granulomatosis])[6,16] account for most cases of autoimmune DAH. Both GPA and MPA are often linked to antineutrophil cytoplasmic antibodies (ANCA)[13,16] and are encompassed in the term *ANCA-associated vasculitis (AAV)*.[17] Eosinophilic granulomatosis with polyangiitis (EGPA) (formerly Churg-Strauss Syndrome) is included as an AAV, even though EGPA is only rarely associated with DAH.[17–20] Other causes of autoimmune DAH include anti–glomerular basement membrane (anti-GBM) antibody disease,[21–25] connective tissue disease (CTD, principally systemic lupus erythematosus [SLE]),[26–30] and exogenous agents or drugs.[31–34] In many of these disorders, rapidly progressive glomerulonephritis (RPGN) is concomitantly present.[35,36] In most patients with autoimmune DAH and glomerulonephritis (GN), anti-GBM antibody and immune complexes are lacking.[36] The term *pauci-immune glomerulonephritis* has been used to refer to this group of patients, who encompass a heterogenous group of disorders.[36–38] Interestingly, rare patients with “pauci-immune capillaritis” have DAH but no extrapulmonary involvement.[39] Idiopathic pulmonary hemosiderosis, a rare cause of recurrent DAH with no renal or extrapulmonary component, occurs primarily in children[40–42] and remains a diagnosis of exclusion.

TABLE 68-1 Etiology of Autoimmune Diffuse Alveolar Hemorrhage

Anti–glomerular basement membrane antibody disease (Goodpasture syndrome)
Antineutrophil cytoplasmic antibody (ANCA)-mediated vasculitis (e.g., granulomatosis and polyangiitis [formerly Wegener granulomatosis], microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis [formerly Churg-Strauss syndrome], pauci-immune glomerulonephritis)
Idiopathic rapidly progressive glomerulonephritis
Collagen vascular disease (e.g., systemic lupus erythematosus)
Immunocompromised status (e.g., bone marrow transplant, AIDS)
Exogenous agents or drugs (e.g., trimellitic anhydride, isocyanates, D-penicillamine, cocaine)
Idiopathic pulmonary hemosiderosis (pathogenesis unknown)

Differentiating these diverse syndromes can usually be accomplished by serologic studies and by kidney biopsy. In such cases, lung biopsy is not required. GN can be demonstrated in the great majority of patients with DAH complicating MPA,[1,12,13] GPA,[1,16] or anti-GBM disease.[24] By contrast, the kidneys may be spared in DAH associated with CTD,[26,28,29] stem cell transplant recipients,[43–46] or immunocompromised patients.[47,48] Urinalysis (to look for microscopic hematuria, red cell casts, and proteinuria) and measurement of renal function should always be done in the diagnostic evaluation of DAH. Findings consistent with GN warrant a prompt and aggressive evaluation that should include percutaneous needle biopsy of the kidney.

CLINICAL FEATURES OF AUTOIMMUNE ALVEOLAR HEMORRHAGE

Irrespective of etiology, the clinical, radiographic, and histopathologic features of DAH may be similar.[1–3] Classic findings are hemoptysis, diffuse alveolar infiltrates, hypoxemia, renal failure, and iron-deficiency anemia.[3] However, the clinical spectrum is wide, and many of these features may be subtle or absent. In this context, the diagnosis of DAH may be difficult, as signs and symptoms overlap with diverse etiologies of diffuse alveolar infiltrates. Prompt diagnosis and institution of therapy is vital to avert early mortality from DAH and late sequelae from end-stage renal disease (ESRD). Chest radiographs typically reveal bilateral alveolar infiltrates, often with a batwing appearance. However, focal, and even unilateral, patterns indistinguishable from pneumonia may occur.[49] Following cessation of bleeding, infiltrates markedly improve or normalize within 24 to 72 h (Fig. 68-1). A presumptive diagnosis of DAH can often be made by a combination of clinical and serologic findings and bronchoalveolar lavage (BAL) fluid. Grossly bloody BAL fluid (with progressively more blood with serial aliquots),[2,3,49] large numbers of hemosiderin-laden macrophages,[2,47] and the absence of purulent secretions or ancillary evidence for infection strongly support DAH as the cause of pulmonary infiltrates. Ancillary studies including serologies, renal function tests, and urinalysis may support the diagnosis.

DIAGNOSIS

Diagnosis of an alveolar hemorrhage syndrome may entail lung or kidney biopsy, as discussed below.

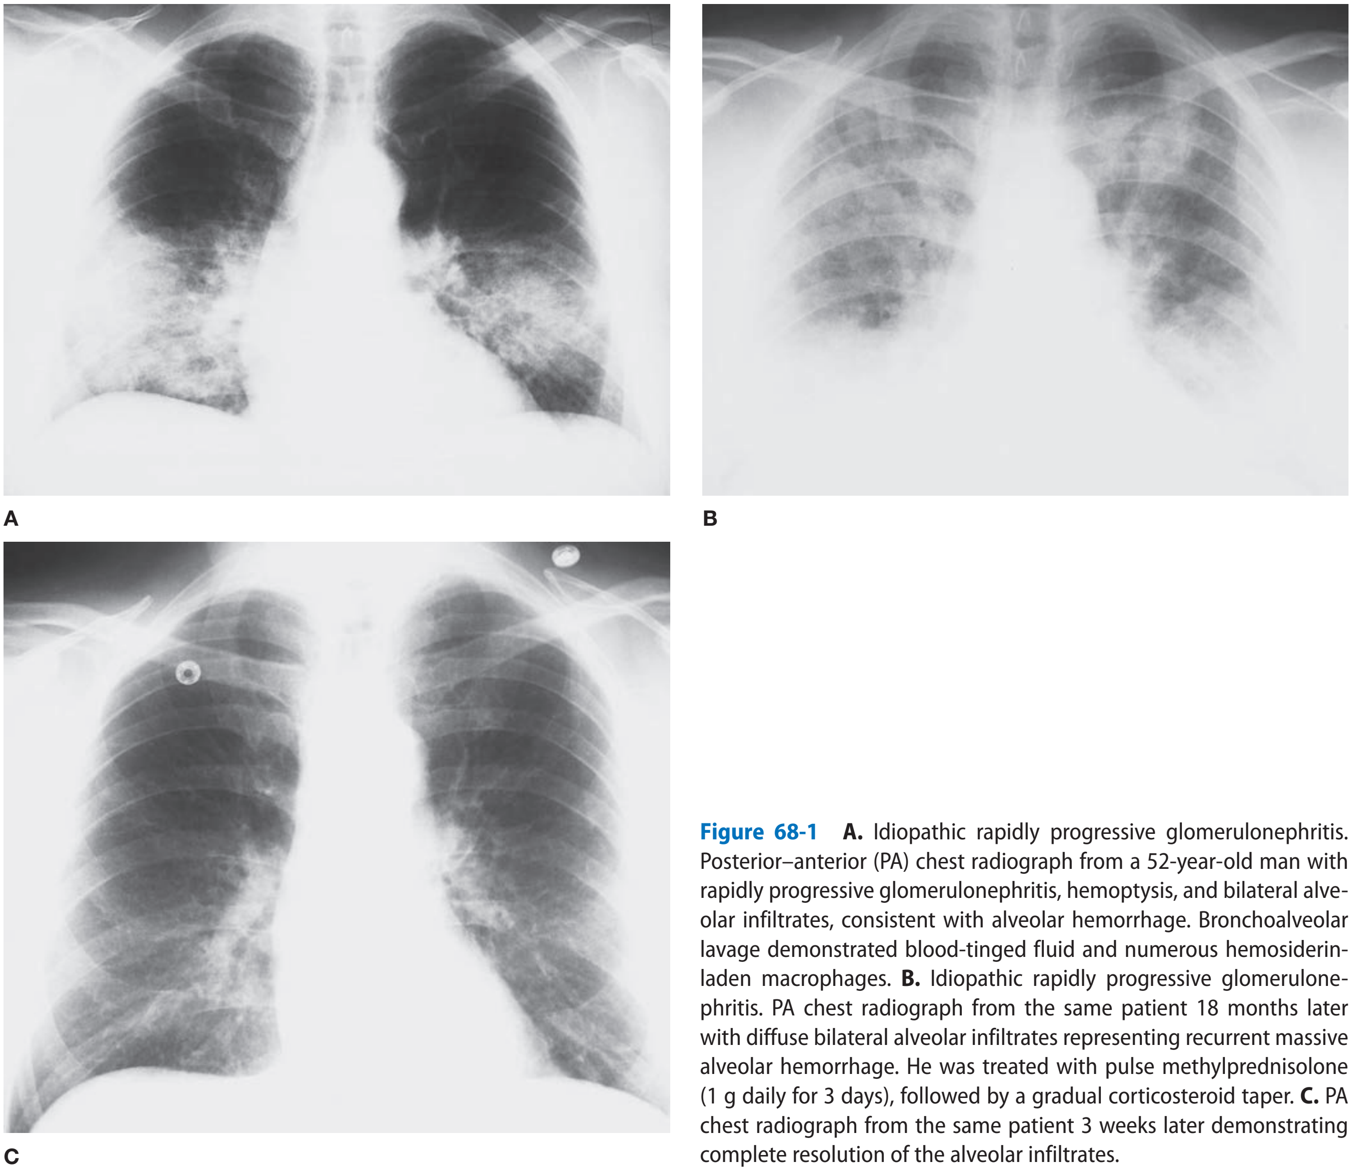

Figure 68-1 **A.** Idiopathic rapidly progressive glomerulonephritis. Posterior–anterior (PA) chest radiograph from a 52-year-old man with rapidly progressive glomerulonephritis, hemoptysis, and bilateral alveolar infiltrates, consistent with alveolar hemorrhage. Bronchoalveolar lavage demonstrated blood-tinged fluid and numerous hemosiderin-laden macrophages. **B.** Idiopathic rapidly progressive glomerulonephritis. PA chest radiograph from the same patient 18 months later with diffuse bilateral alveolar infiltrates representing recurrent massive alveolar hemorrhage. He was treated with pulse methylprednisolone (1 g daily for 3 days), followed by a gradual corticosteroid taper. **C.** PA chest radiograph from the same patient 3 weeks later demonstrating complete resolution of the alveolar infiltrates.

■ The Role of Lung Biopsy

The role of lung biopsy in the diagnosis of DAH and the determination of its etiology is controversial. We believe the risks of open or thoracoscopic lung biopsy are excessive in patients with severe DAH and respiratory failure. Postoperative complications, such as infection and air leaks, may be exacerbated by corticosteroids (CS) or immunosuppressive agents (IA) used to treat many of these immune-mediated DAH syndromes. Furthermore, histologic features are usually nonspecific. Predominant findings are extensive intra-alveolar hemorrhage and necrotizing pulmonary capillaritis (endotheliitis) (Fig. 68-2).[2] Capillaritis is characterized by neutrophilic infiltration of capillaries, fragmented neutrophils (leukocytoclasis), and necrosis of the capillary walls[2] (Fig. 68-3). Loss of the integrity of the alveolar-capillary basement membrane results in leakage of red blood cells and neutrophils into the alveolar space.[3] Hemosiderin-laden macrophages (siderophages) accumulate within the alveolar spaces and interstitium; their presence is a clue to prior episodes of alveolar hemorrhage[2] (Figs. 68-2B, 68-2C, and 68-4).

Capillaritis was initially described as a marker of systemic vasculitis, but it may also be observed in myriad disorders associated with DAH (e.g., SLE,[26] CTD,[3] anti-GBM disease,[21,24] stem cell/bone marrow[43,44] or lung transplantation,[50] and drug-induced DAH).[31,49,51] An associated venulitis and arteriolitis may sometimes be present, but larger vessels are spared.[2] Capillaritis is subtle and often overshadowed by DAH filling the alveolar spaces.

Pulmonary capillaritis can be diagnosed by transbronchial biopsy, but this diagnosis is made with greater confidence when larger biopsy specimens are obtained by video-assisted thoracoscopy or limited thoracotomy.[2] Additional pathologic features may be seen in patients with underlying granulomatous vasculitis (e.g., granulomas, necrosis, eosinophils).[2] Nongranulomatous inflammation in airways and lung interstitium, interstitial fibrosis, diffuse alveolar damage (DAD), fibrinous pleuritis, and organizing pneumonia have also been described in DAH associated with AAV.[2] It should be emphasized that histologic findings of alveolar hemorrhage and capillaritis, although distinctive, are nonspecific.[2] Immunofluorescent (IF) stains (of lung or kidney) or serologic markers (e.g., anti-GBM antibody, ANCA) are required to differentiate the various causes of autoimmune DAH[1,2] (Table 68-2). Linear deposits of immunoglobulin G (IgG) along alveolar septa are pathognomonic for anti-GBM disease.[21,24] A granular or "lumpy-bumpy" pattern of immune complex deposits may be seen in SLE, systemic necrotizing vasculitis, or immune complex–mediated idiopathic RPGN.[2] In ANCA-associated capillaritis, immune complexes are usually lacking (hence

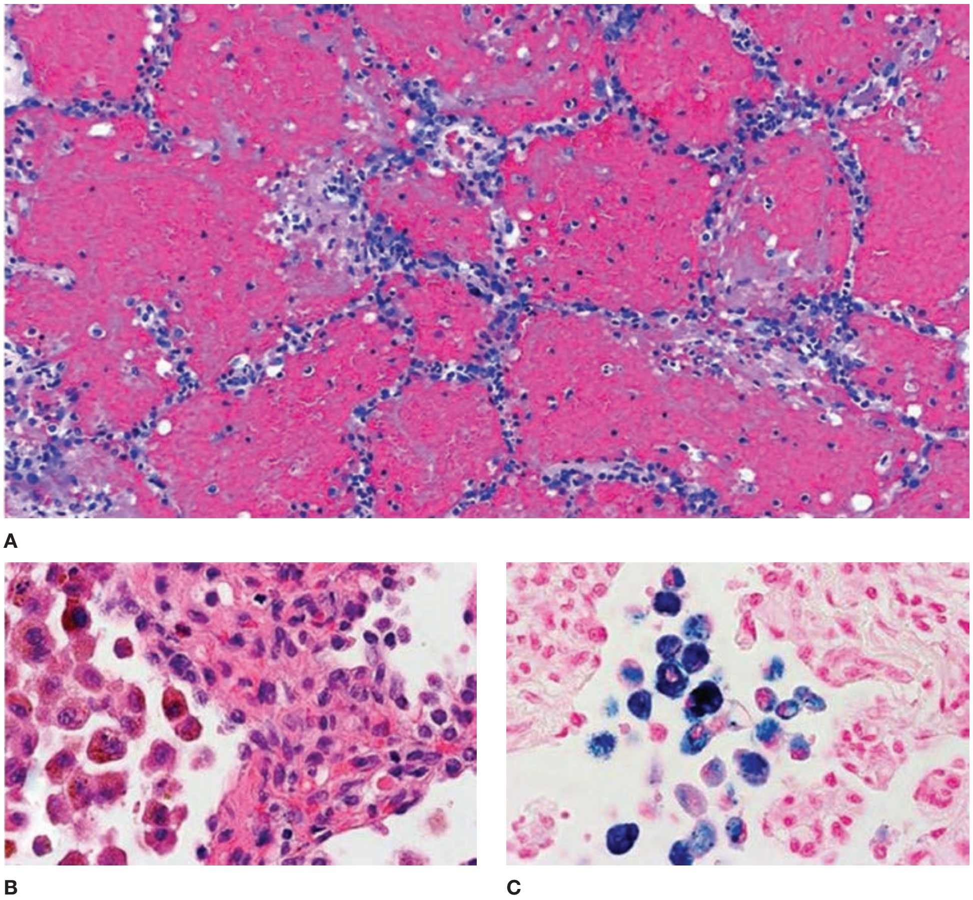

Figure 68-2 Alveolar hemorrhage. **A.** Acute hemorrhage with blood filling alveolar spaces (H&E stain, ×40). **B.** Pigment-laden macrophages (H&E stain, ×200) shown in **C** to be full of iron (blue cytoplasm) indicative of prior hemorrhage (Prussian blue stain, ×200).

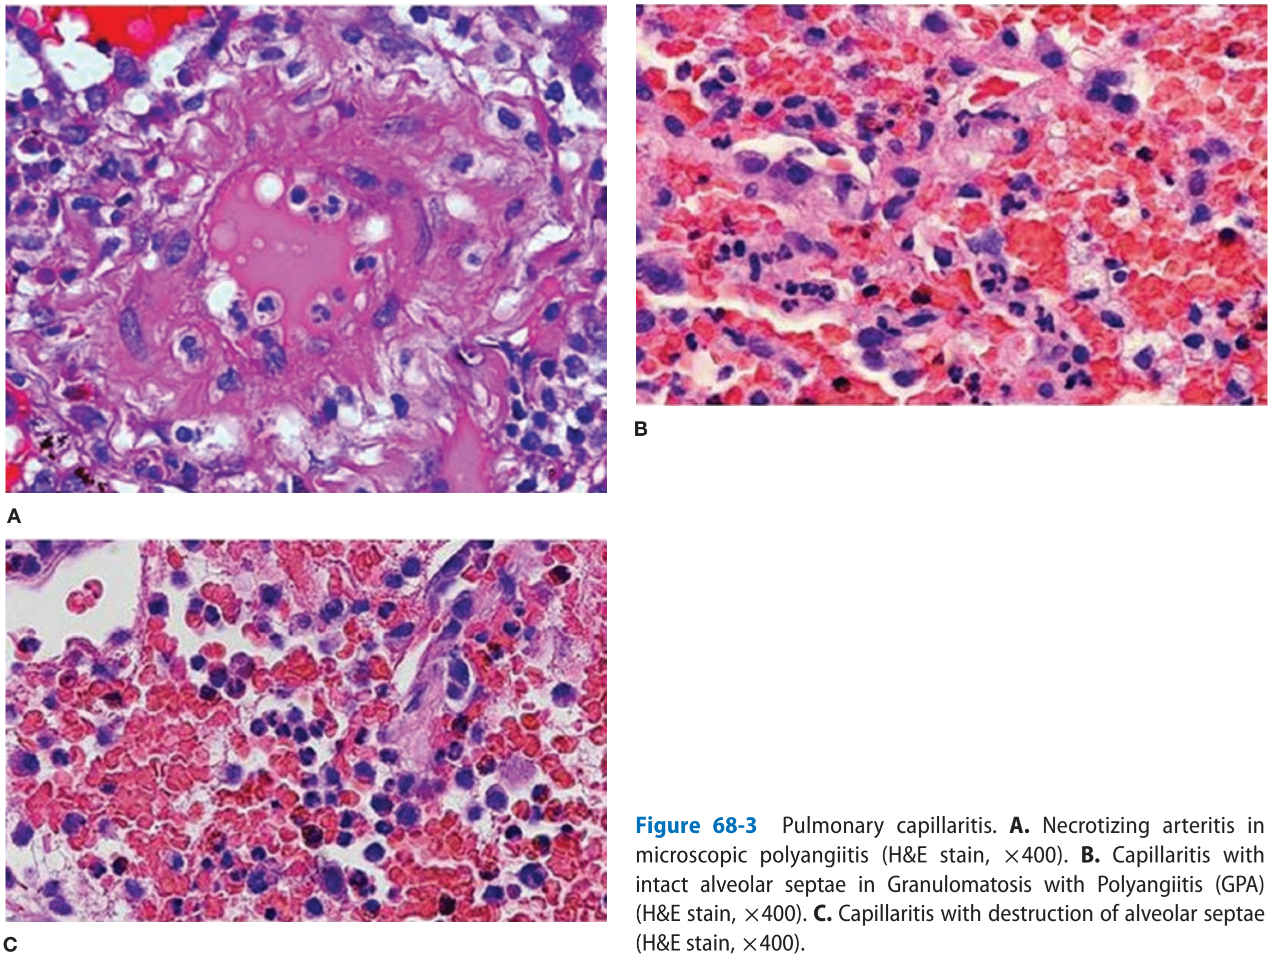

Figure 68-3 Pulmonary capillaritis. **A.** Necrotizing arteritis in microscopic polyangiitis (H&E stain, ×400). **B.** Capillaritis with intact alveolar septae in Granulomatosis with Polyangiitis (GPA) (H&E stain, ×400). **C.** Capillaritis with destruction of alveolar septae (H&E stain, ×400).

the term *pauci-immune*).[12,13] When immune DAH is suspected, a portion of the lung biopsy can be frozen for IF stains, but IF stains of lung tissue are logistically difficult, and nonspecific background staining may lead to misinterpretation. When GN is present concomitantly, kidney IF stains are more sensitive and reliable.

Despite the greater accuracy of surgical lung biopsy in evaluating DAH, flexible bronchoscopy with BAL is usually adequate to exclude infectious etiologies and support the diagnosis of DAH with a much better safety profile.[2,49] Bloody or serosanguinous BAL fluid (consistent with active or recent bleeding)[3,49] or hemosiderin-laden macrophages[2] (a clue to prior episodes of alveolar hemorrhage) may be sufficient to justify initiation of therapy provided clinical and serologic features are consistent. Thoracoscopic lung biopsy may be useful in *non-critically ill* patients with suspected DAH when ancillary studies, kidney biopsy, and BAL are nondiagnostic.[2]

■ The Role of Percutaneous Kidney Biopsy

Necrotizing GN is a cardinal (albeit nonspecific) feature of most immune-mediated DAH syndromes.[8,38] The histologic spectrum is varied, ranging from mild mesangial thickening to severe crescentic GN.[38] Vasculitis of renal arterioles is rarely found, even in granulomatous vasculitides. Because of the strong association of autoimmune DAH and GN, percutaneous kidney biopsy should be performed in any patient with suspected DAH who has abnormalities on urinalysis or renal function tests. Conventional hematoxylin and eosin (H&E) stains are nonspecific, but the demonstration of glomerular inflammation with necrosis and crescents supports the diagnosis of an immune-mediated etiology[52] (Fig. 68-5). IF stains may clarify the nature of the underlying disorder. Bright, linear IF staining along GBMs is pathognomonic for anti-GBM disease[22,24] (Fig. 68-6). A lumpy-bumpy IF pattern, consistent with deposits of immune complexes, is found in some cases of CTD[26] and in idiopathic immune complex–mediated GN.[53] Negative IF stains are characteristic of pauci-immune GN of necrotizing vasculitis.[37,38] Serologies are critically important in defining the underlying disorder responsible for DAH (particularly ANCA, anti-GBM antibody, and antinuclear antibodies). Recognizing the different pathogenetic mechanisms of these DAH syndromes is important, as the prognosis and treatment strategies may differ.

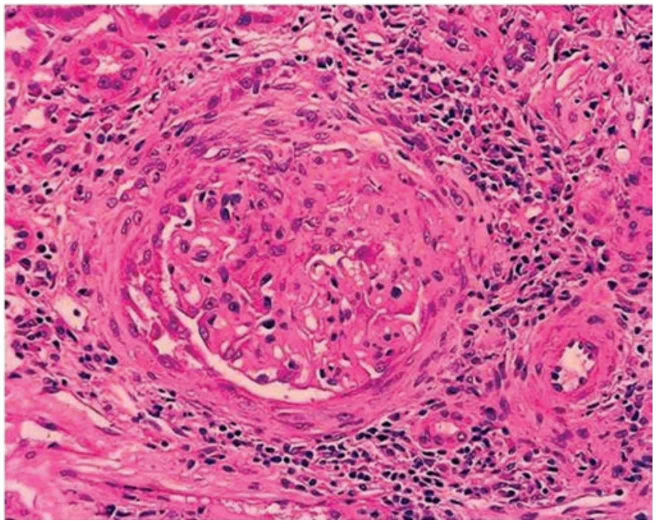

Figure 68-5 Segmental and necrotizing crescentic glomerulonephritis due to vasculitis (H&E).

THERAPY OF IMMUNE-MEDIATED ALVEOLAR HEMORRHAGE

Irrespective of etiology, the most immediate concern in patients with severe DAH is to control intrapulmonary bleeding, which may be fatal.[8] Measures to ensure adequate oxygenation are essential. Mechanical ventilation (MV) may be necessary in fulminant cases of DAH, to prevent death due to refractory hypoxemia. Priorities

TABLE 68-2 Autoimmune Diffuse Alveolar Hemorrhage: Pathology and Serology

	Lung Pathology		Renal Pathology		
	Histopathology	Immunofluorescence	Histopathology	Immunofluorescence	Serology
ABMA disease (Goodpasture syndrome)	± Capillaritis	Linear	Variable	Linear	ABMA (± p-ANCA)
Granulomatosis with polyangiitis	Capillaritis (± granulomatous)	Negative	Segmental necrosis, crescents	Pauci-immune	ANCA (c-ANCA ⋙ p-ANCA)
Microscopic polyangiitis	Capillaritis	Negative	Segmental necrosis, crescents	Pauci-immune	ANCA (p-ANCA or c-ANCA)
Systemic lupus erythematosus	Capillaritis	Granular	Variable	Granular	ANA
Idiopathic pulmonary hemosiderosis	± Capillaritis	Negative	Normal	—	Negative

ABMA, anti–basement membrane antibody; ANA, antinuclear antibody; ANCA, antineutrophil cytoplasmic antibody; p-ANCA, perinuclear antineutrophil cytoplasmic antibody; c-ANCA, cytoplasmic antineutrophil cytoplasmic antibody.

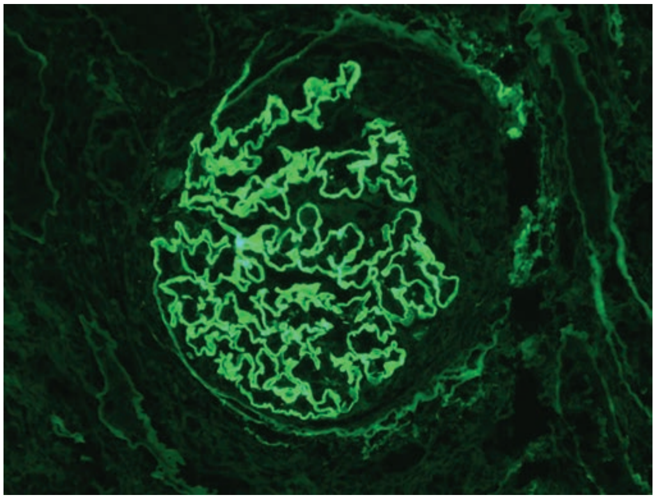

Figure 68-6 Linear immunofluorescent staining along glomeruli due to deposition of anti–glomerular basement membrane (anti-GBM) antibody.

should be airway protection, rapid hemodynamic stabilization, and intubation with a large (≥8 mm) endotracheal tube for severe cases requiring MV.[54] This allows for effective ventilation and facilitates the passage of a bronchoscope for suctioning as well as tamponade. Transfusion of red blood cells may be required to maintain an acceptable hematocrit and adequate blood pressure. In patients with severe hypoxemia despite MV, extracorporeal membrane oxygenation (ECMO) may be life-saving.[55–58]

Immune-mediated DAH (regardless of etiology) is a medical emergency and requires prompt administration of IV "pulse" methylprednisone (MP) 500 to 1000 mg daily for 3 days, even while pursuing a diagnostic workup.[49,59] Delaying pulse therapy in a critically ill patient for even a few hours may be catastrophic. Following initiation of therapy, bleeding may resolve quickly (often within 24 to 72 h) (Fig. 68-7). Following the 3-day pulse, the dose of MP should be reduced to approximately 60 mg per day (or equivalent) until control of the bleeding and extrapulmonary manifestations has been achieved. The subsequent dose and rate of corticosteroid (CS) taper need to be individualized, based upon clinical, radiographic, and serologic response. Optimally, the dose of CS should be reduced to 5 mg daily within 6 months, as data from the PEXIVAS Trial (including patients with AAV [GPA or MPA] with renal involvement or DAH) demonstrated that reduced dose of CS was noninferior to "standard" dose of CS and resulted in fewer infections.[60] For GPA, MPA, and anti-GBM disease, a second IA (typically, cyclophosphamide [CYC])[35,49,61] is added. For GPA and MPA, rituximab (RTX) may be given in lieu of CYC, as RTX is at least as effective, and possibly more effective than CYC,[62,63] with potentially less toxicity. Treatment of anti-GBM disease includes CS plus oral CYC (2 mg/kg/d), in addition to therapeutic plasma exchange (TPE; see below).[24] The role of IA or RTX for other causes of DAH or pulmonary renal syndromes has not been elucidated, as data are limited. Prophylaxis against *Pneumocystis jirovecii* is mandatory in patients receiving dual-agent immunosuppression. TPE is a central component of therapy for anti-GBM disease,[21,23,64] but its role for other disorders associated with DAH remains controversial[65] (see "ANCA-Associated Vasculitis," below).

Although data are limited to small series and case reports, anecdotal successes have been cited with recombinant activated factor VIIa (rFVIIa) in fulminant DAH secondary to vasculitis, anti-GBM disease, and SLE.[1,66,67] However, this agent does not have a primary role in DAH.

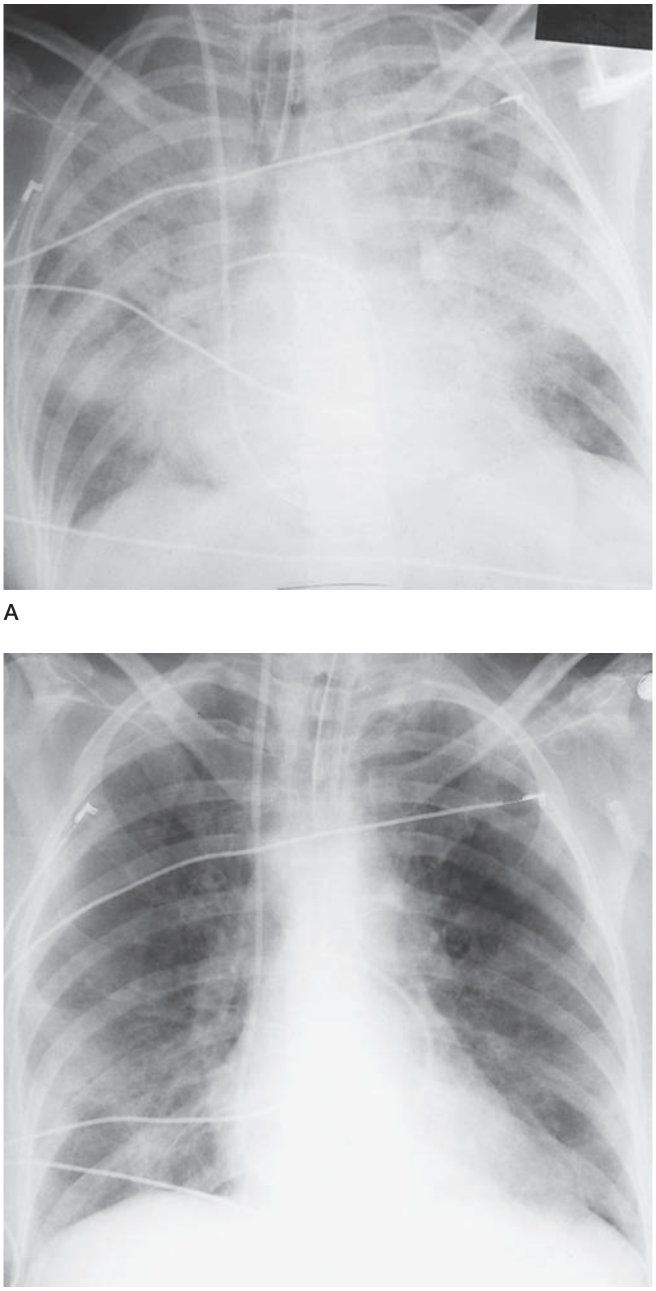

Figure 68-7 **A.** Alveolar hemorrhage due to microscopic polyarteritis (MPA). Posterior–anterior (PA) chest radiograph demonstrating massive alveolar infiltrates involving all lobes. Because of the severity of respiratory failure (requiring 16 cm H_2O of positive end-expiratory pressure to achieve acceptable oxygenation), no lung biopsy was performed. Urinalysis demonstrated numerous red cells and occasional red cell casts. Serum creatinine was 1.4 mg%. Pulse methylprednisolone (1 g daily × 3 days) was initiated, and renal biopsy was scheduled for the following morning. **B.** Alveolar hemorrhage due to MPA. PA chest radiograph from the same patient 12 h following initiation of pulse methylprednisolone. Marked improvement in alveolar infiltrates is evident. Renal biopsy demonstrated glomerulonephritis and a necrotizing vasculitis involving renal arterioles; no granulomas were present. Cyclophosphamide (2 mg/kg/d) was instituted, and corticosteroids were continued. Within 5 days, the infiltrates had cleared completely, and serum creatinine was 0.6 mg%.

SPECIFIC SYNDROMES

In the sections that follow, we discuss each of the autoimmune DAH syndromes.

Anti-GBM Disease (Goodpasture Syndrome)

Anti–glomerular basement membrane (anti-GBM) disease (Goodpasture syndrome), the prototype of pulmonary–renal syndromes, accounts for 18% to 32% of immune-mediated DAH.[22,24,68] This was the first disorder in which a primary role of antibodies was recognized as a cause of renal and/or pulmonary injury.[64] The demonstration of anti-GBM antibodies in tissue (typically kidney)[24,69] or in serum[21,24] is the cornerstone of the diagnosis. Classically, anti-GBM disease manifests as DAH and RPGN.[21,22,24,69] In 30% to 50% of patients with anti-GBM disease, GN occurs *without* DAH; DAH alone is rare (<5%).[21,24,68]

Epidemiology

Anti-GBM disease typically affects individuals between 20 and 45 years of age with a distinct male predominance.[21,24] The incidence has been estimated as 1 to 3 cases per million population per year.[70–72] Data from hospitalized patients in the United States identified 964 cases of anti-GBM disease from 2003 to 2014, for an overall prevalence of 10.3 cases per million admissions.[72]

Pathogenesis

The pathogenesis of anti-GBM disease is unknown, but both genetic[24] and environmental factors[73] may play roles. Patients with anti-GBM disease preferentially express certain immunoglobulin Gm allotypes, and links between anti-GBM disease and the HLA-DR2 histocompatibility antigen have been noted.[24,74] Exposure to hydrocarbon-containing solvents, hard-metal dust, chlorine gas, D-penicillamine,[15,21,24,68] cigarette smoke,[24] cocaine and amphetamine,[24] antecedent viral illnesses (particularly influenza),[24] and use of alemtuzumab[75] have been cited as possible risk factors.

Clinical Features

The clinical expression of anti-GBM disease is highly variable. Most patients present with progressive dyspnea, diffuse alveolar infiltrates, and hypoxemia; hemoptysis occurs in 45% to 94%.[21,24,68] Glomerulonephritis is a cardinal feature.[24,64,76] Microscopic hematuria, red cell casts, or proteinuria are almost always present. Gross hematuria occurs in up to 41% of patients.[21,24] Azotemia is noted in 55% to 71% of patients at presentation.[15,24] Fatigue and weakness are common.[21] In the absence of therapy, progressive renal insufficiency ensues, often resulting in ESRD within days to weeks of the onset of symptoms.[15,24] Oliguria, severe renal failure, or greater than 50% crescents on renal biopsy are associated with a poor prognosis and low rate of recovery of renal function.[15,21,24,69] The course may be fulminant, with severe renal failure and explosive, life-threatening DAH.[15,21,24] Chest radiographs typically reveal dense bilateral alveolar infiltrates, often with air-bronchograms.[24] With cessation of bleeding, infiltrates may resolve within 24 to 36 h. Pleural effusions are rare and suggest an alternative diagnosis. Pulmonary function tests are rarely helpful in the acute setting of DAH.[21,24] Bloody or serosanguineous BAL fluid (that worsens with serial aliquots) suggests DAH but is nonspecific.[2] Anemia is present in more than 90% of cases and may be profound. Serum iron and ferritin levels are usually decreased, reflecting diminished iron stores. Factors associated with a higher incidence of DAH include exposure to high concentrations of oxygen, upper respiratory tract infections, and increased hydrostatic (pulmonary capillary) pressures.[15,21]

Establishing the Diagnosis

Serologic assays for anti-GBM antibody are invaluable to confirm the diagnosis and monitor the adequacy of therapy.[21,24] Radioimmunoassays or enzyme-linked immunosorbent assays (ELISA) for anti-GBM antibody are highly sensitive (>95%) and specific (>97%)[15,21,24] but are performed in only a few laboratories. Results are usually not available for 2 to 4 days. Since delay in the institution of therapy may preclude a favorable outcome, percutaneous renal biopsy is usually performed while awaiting the results of serum assays.[24]

Histopathology

Percutaneous kidney biopsy is the preferred invasive procedure to substantiate the diagnosis of anti-GBM disease.[24] Light microscopy demonstrates a proliferative or necrotizing GN, often with cellular crescents.[21,24] Over time, the crescents may fibrose, and frank glomerulosclerosis, interstitial fibrosis, and tubular atrophy may be observed.[24,69] Although these microscopic features are nonspecific, IF stains are the cornerstone of the diagnosis. Bright linear deposits of IgG and complement (C3) along the glomeruli are pathognomonic of anti-GBM disease[21,24] (Fig. 68-6). All four subclasses of IgG are represented, but IgG_1 and IgG_3 predominate.[24] Rare cases of linear deposits of IgM or IgA have been described.[68] Lung biopsies are rarely necessary,[2,21,24] as the histologic features on renal biopsy are usually adequate to establish the diagnosis. When lung biopsy has been done, extensive hemorrhage predominates[2] with accumulation of hemosiderin-laden macrophages within the alveolar spaces.[2] Foci of DAD and capillaritis also may be found.[2] Interstitial or intra-alveolar inflammation is minimal or absent. Extensive necrosis or large-vessel vasculitis is not found. Similar histopathologic features may be seen with a wide gamut of immune-mediated DAH syndromes.[2] IF stains of lung tissue may be diagnostic, provided a clear linear pattern of immunofluorescence is present. However, IF stains are technically difficult in lung tissue, and autofluorescence may obscure the linear IgG deposits.

Pathogenesis

Antibodies are directed against the α3 chain of type IV collagen, an antigen highly expressed in both alveolar and glomerular basement membranes.[24,74] Anti-GBM antibodies bind the GBM and activate complement, initiating an inflammatory pathway that elicits injury.[24] Injury to kidney (and/or lung) basement membranes results in increased capillary permeability, exposing the Goodpasture antigen (α3 chain), which is then recognized as foreign, eliciting a T-helper cell response.[68,73] In addition to circulating antibodies, autoreactive T lymphocytes directed against the α3 antigen are key mediators for development of RPGN.[24,68] Up to one-third of patients with circulating anti-GBM antibodies have concomitant ANCA (usually MPO).[24,52] Other serologic studies are negative or nondiagnostic.

Treatment

Before the availability of current therapy and renal dialysis, mortality exceeded 90%.[15] Therapeutic plasma exchange (TPE) was introduced as a therapeutic option for anti-GBM disease in the 1970s[64] and was quickly adopted worldwide and incorporated in all clinical trials. Currently, with the combination of TPE, CS, and CYC, 5-year survival exceeds 80%.[15,21,24,69,72] Because of the rarity of anti-GBM syndrome, only one small randomized trial compared immunosuppressive therapy (CS + CYC) with the *combination* of CS + CYC *plus* TPE.[64] In that study, TPE plus CS + CYC was associated with more rapid disappearance of anti-GBM antibody and improved renal function compared to treatment with CS + CYC *alone.*[64] The optimal extent and duration of TPE have not been defined. Most investigators advocate TPE daily or every other day for 2 to 3 weeks, until the clinical course has improved and serum anti-GBM antibodies are nondetectable.[24,77] Immunosuppressive therapy is required to inhibit antibody production and rebound hypersynthesis that may occur following discontinuation of TPE.[24]

Treatment of acute, life-threatening DAH in anti-GBM disease is similar to that of other autoimmune disorders. Pulse MP (typically 1 g daily for 3 days) is given, followed by a gradual taper of CS.[21] CYC is initiated once the diagnosis of anti-GBM disease is substantiated. Most investigators favor CYC over other IA,[15,21,24] but studies comparing other IAs in anti-GMB disease have not been done. RTX has been used as an adjunct to conventional therapy, with anecdotal successes in some cases,[78] but data are insufficient to recommend RTX in lieu of CYC.[24] CYC is maintained for the duration of therapy, unless complications such as leukopenia necessitate dose reduction. CS are gradually tapered over several months. With treatment, circulating anti-GBM antibodies usually clear within 8 to 12 weeks and self-tolerance is restored.[24,68] This tolerance may be achieved by regulatory CD4+ and CD25+ T cells[24,68] or anti-idiotypic (blocking) antibodies,[73] but this remains speculative.

Immunosuppressive therapy may be discontinued within 3 to 6 months provided a sustained remission has been achieved and anti-GBM antibodies have disappeared.[15,24] Early relapse (within the first 2 months) may occur when circulating antibodies are still present. This typically manifests as DAH. Risk factors for relapse include infection, volume overload, and cigarette smoking.[24] Late recurrence, associated with renewed antibody synthesis following a remission, is rare.[21,24]

In summary, aggressive therapy with TPE, CS, and CYC has dramatically improved prognosis in anti-GBM disease.[21,24,72] With this approach, 5-year survival exceeds 80%, although >50% of patients remain dialysis-dependent at 1+ years.[21,24,72,74] Factors associated with increased inpatient mortality include age older than 70 years, sepsis, or the development of respiratory, circulatory, renal, or liver failure, whereas factors associated with reduced inpatient mortality include more recent year of hospitalization and TPE.[72]

Early recognition and treatment of anti-GBM disease are critical, as the prognosis for recovery of renal function depends upon the initial extent of injury.[24,52,69,76,79] Recovery of renal function can be expected in patients with minor functional impairment.[79] By contrast, patients manifesting initial serum creatinine greater than 4 mg/dL, oliguria, or greater than 50% crescents on renal biopsy rarely recover and usually progress to ESRD requiring chronic dialysis.[24,52,69,76] In one study of 71 patients with anti-GBM disease (all of whom were treated with CS, CYC, and TPE), renal survival was linked to extent of renal failure at presentation.[25] Renal survival rates at 1 year were as follows: 8% among 39 patients requiring dialysis at presentation; 82% among 13 patients with creatinine >5.7 mg/dL but not requiring dialysis; and 95% among 19 patients with initial serum creatinine <5.7 mg/dL.[25] In a study of 123 cases of anti-GBM disease from 6 centers worldwide from 1986 to 2015, the extent of normal glomeruli and extent of interstitial infiltrate on renal biopsy and need for dialysis at presentation predicted the incidence of ESRD at follow-up.[79] Histologic class on renal biopsy predicted long-term renal survival ($p < 0.001$). Among 15 patients with ≥50% normal glomeruli on renal biopsy, only 1 developed ESRD. In sharp contrast, cases with >50% sclerosis of glomeruli or 100% crescents on renal biopsy did not recover from dialysis dependence.[79] Renal transplantation has been successful in patients with ESRD, provided serum anti-GBM antibodies have been undetectable for a minimum of 6 months.[24,80]

■ Systemic Vasculitis

DAH is a common complication of microscopic polyangiitis (MPA)[1,12,13,49] and GPA[16] and rarely complicates eosinophilic granulomatosis with polyangiitis (EGPA) (formerly Churg-Strauss syndrome),[17,19] Behçet's disease,[81] mixed cryoglobulinemia,[82] Henoch-Schoenlein purpura,[1,83] and other systemic necrotizing vasculitides.[49,84] Classic polyarteritis nodosa (PAN) rarely involves the lung.[2] Necrotizing small-vessel vasculitis accounts for the majority of autoimmune DAH syndromes.[49,85] RPGN is usually present in each of these DAH syndromes, but the disease is sometimes limited to the kidneys or lungs. Circulating antibodies directed against cytoplasmic components of neutrophils and monocytes (ANCA) have been detected in most patients with these "pulmonary renal syndromes,"[8,53,84,86] suggesting a common pathogenesis and mechanism of lung injury in these diverse vasculitic disorders.

ANCA-Associated Vasculitis

More than two-thirds of patients with pulmonary–renal syndromes are mediated by ANCA antibodies without anti-GBM or immune complexes (i.e., pauci-immune).[1,8,10,49,53,61,84] Depending upon clinicopathologic features, some cases with pauci-immune GN and DAH may meet criteria for GPA or EGPA, while others exhibit a multisystemic small-vessel vasculitis but lack granulomatous inflammation of the respiratory tract. In this context, the term microscopic polyangiitis (MPA) is used.[12,13] The availability of serum assays for ANCA has profoundly influenced the classification of immune DAH and GN. ANCA-positive patients with pauci-immune DAH and GN are now considered to have MPA.[13] The spectrum of AAV is not limited to patients with pulmonary–renal syndromes but includes individuals with MPA limited to the lung (i.e., manifesting as DAH) or kidney (i.e., necrotizing GN).[13] Brief definitions of AAV are outlined below.

■ Granulomatosis with Polyangiitis (GPA)

Formerly called Wegener granulomatosis, GPA is the most common of the pulmonary vasculitides. Typically, GPA involves the upper respiratory tract (e.g., sinuses, ears, nasopharynx, oropharynx, trachea), lower respiratory tract (bronchi and lung), and kidney, with varying degrees of disseminated vasculitis.[16,87] The annual incidence of GPA has been estimated as 4 to 12 cases per million.[16,87] Severe DAH is an uncommon (<20%) complication of GPA, reflecting diffuse injury to the lung microvasculature (i.e., capillaritis)[49,62] (Fig. 68-8). In this context, RPGN is present in more than 90% of patients.[16,87]

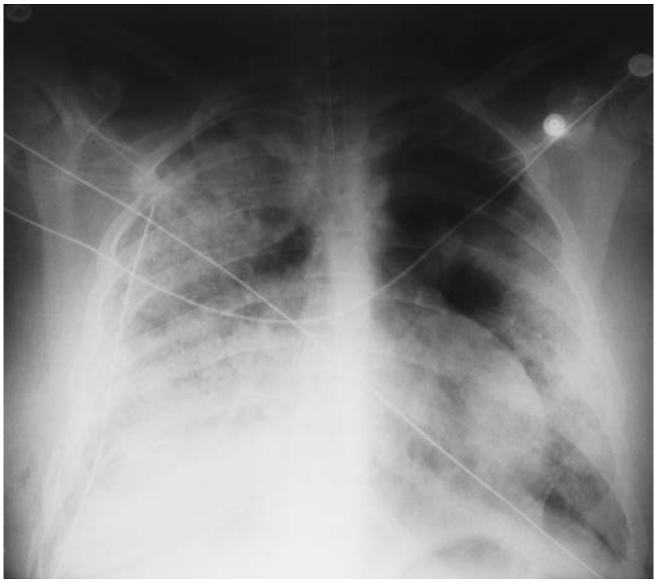

Figure 68-8 Granulomatosis with polyangiitis (GPA) (formerly called Wegener granulomatosis). Posterior–anterior chest radiograph demonstrated bilateral alveolar infiltrates in a 13-year-old girl with hemoptysis and respiratory failure. A right chest tube is in place from an open lung biopsy performed 2 days earlier. Open lung biopsy demonstrated capillaritis and massive alveolar hemorrhage. Pulse methylprednisolone, followed by oral cyclophosphamide and prednisone, was associated with a complete remission.

The salient histopathologic features of GPA include small-vessel vasculitis (involving capillaries, arterioles, venules), geographic necrosis, hemorrhagic infarcts, a mixed inflammatory cellular infiltrate, and a granulomatous component.[16,87] Circulating c-ANCAs (PR-3 epitope) have been detected in more than 90% of patients with active generalized GPA and in 40% to 70% with active regional GPA.[16,86–88]

Beginning in the early 1970s, oral CYC (2 mg/kg/d) plus prednisone was the treatment of choice for GPA for more than 4 decades.[16,87,89] With this regimen, remissions were achieved in 70% to 93% of patients, with early mortality rates of less than 15%.[16,87,89–92] After sentinel studies in 2003,[90] less toxic IA, such as azathioprine (AZA)[90,91] or methotrexate (MTX),[91] were substituted for CYC after 3 to 6 months, assuming complete remissions were achieved. Treatment was continued for a minimum of 12 to 18 months (total duration).[16,87] MTX was also used in patients with limited disease or those experiencing significant toxicity from CYC.[92,93] In 2010, two sentinel studies showed that RTX was as effective as, and possibly more effective than, CYC for GPA and AAV.[62,63] Since then, most clinicians favor RTX over CYC, owing to outstanding efficacy and less morbidity.[94–97]

RTX is used as induction therapy, usually with CS, although CS can be discontinued within 3 to 6 months if remissions are complete. Further, RTX can be used as *maintenance* therapy for GPA. In a retrospective study, the French Vasculitis Study Group reported 66 cases of CPA who received RTX as induction therapy from 2002 to 2013.[98] At 6 months, 79% had responded (complete [38%] or partial [41%]). These responders received 500 mg RTX at 6, 12, and 18 months and were followed for a mean of 34.2 months.[98] Relapses occurred in 11.2/100 patient-years at a mean of 13.5 months after the last dose of RTX.[98] In a subsequent study, these investigators randomized 115 patients with AAV (GPA [n = 87]; MPA [n = 23]; renal limited AAV [n = 5]) who had achieved complete remissions (CR) with CS and CYC to receive *maintenance* therapy with RTX (500 mg at 0 and 14 days, and thereafter at months 6, 12, and 18) or AZA (dose 2 mg/kg × 12 months, then 1.5 mg/kg × 6 months, then 1.0 mg/kg × 4 months).[97] At 28 months, major relapses occurred in 3 of 57 (5%) cases receiving RTX compared with 17 of 58 (29%) receiving AZA ($p = 0.002$). Serious adverse effects were similar between the study groups ($p = 0.92$). Two patients died (both in the AZA group). Other studies support the use of RTX for both *induction and maintenance* therapy for GPA and MPA.[94–96] Data are sparse and insufficient to assess the role of RTX as therapy (induction or maintenance) for EGPA. TPE has no proven role in GPA, although benefit with TPE and IA was suggested in a single case report with massive DAH.[99]

■ Microscopic Polyangiitis (MPA)

MPA typically presents with GN and pulmonary capillaritis manifesting as DAH.[8,12,13] Clinical and serologic features of MPA overlap with GPA and EGPA.[13,100] MPA is rare, with an annual incidence of 2.1 to 17.5 cases per million.[20,70,101] As its name implies, MPA involves small vessels (arterioles, venules, or capillaries); extension to larger vessels occurs in a minority of cases.[13,85] Small vessels are always spared in classic PAN.[85,102] In contrast to GPA or EGPA, neither granulomas nor eosinophils are prominent in MPA.[13,85]

Circulating ANCA (typically p-ANCA; myeloperoxidase [MPO] epitope) are present in 50% to 90% of patients with MPA,[13,85,100] suggesting a relationship with other AAV. A necrotizing, crescentic, pauci-immune GN is nearly invariably present in MPA[8,13,85] but is rare in classic PAN.[85] DAH occurs in 30% to 50% of patients with MPA and is often the dominant and most life-threatening manifestation.[12,13,100] In a retrospective study from Peking, China, severe DAH developed in 12 of 131 (9.2%) cases of AAV.[8] Associated involved sites included GN (100%); fever and arthralgias/myalgias (91.7%); GI tract (42%); ENT (25%); cardiovascular (16.7%); and nervous system (16.7%). All were treated with CS + CYC; 7 received IV pulse MP. Additional therapies included TPE (41.7%); MV (41.7%); and dialysis (25%). Despite aggressive therapy, 3 died of fulminant DAH during the first week of treatment, and another 4 died of septic shock (n = 2), severe heart failure (n = 1), or systemic fungal infection (n = 1) 10 to 32 days after the onset of DAH.

Treatment for MPA has been similar to GPA, typically employing CS with an IA (typically oral CYC [2 mg/kg/d]).[13,90,100] With this approach, favorable responses have been achieved in more than 80% of patients; 10-year survival exceeds 70%.[13,90,100] By 3 to 6 months, once CR has been achieved, AZA, MTX, or another IA may be substituted for CYC.[13,90] As was discussed in the section on GPA, RTX appears to be as efficacious as CYC-containing regimens for AAV (MPA or GPA)[62,63,94–96] and is considered by many experts to be first-line therapy (in lieu of CYC).

■ ANCA-Associated Pulmonary-Renal Syndromes

The ANCA-associated pulmonary–renal syndromes constitute an important collection of disorders and are discussed below.

Clinical Features

The clinical and radiologic manifestations of ANCA-associated DAH are similar to other immune causes. Acute necrotizing GN is nearly always present, but the renal lesion is nonspecific.[13,37,53,103] Distinguishing the specific underlying disorder may be difficult. The pathologic lesions in AAV share characteristic features, regardless of the organ affected. The three key histopathologic findings are a segmental (focal) distribution of vascular injury, infiltration with neutrophils, and fibrinoid necrosis.[85,100] The latter results from lysis of the vascular wall, allowing plasma coagulation factors to enter the interstitium and come into contact with thrombogenic substances, generating fibrin. Neutrophils that infiltrate vessel walls undergo disruption and karyorrhexis, leading to the typical leukocytoclastic pattern of injury in capillaries and venules.[85] ANCA-associated vascular injury is accompanied by few, if any, immune deposits (pauci-immune).[1,36] However, the presence of immune deposits may be associated with more severe renal injury.[53] The salient lesion of renal vasculitis is a segmental necrotizing GN, usually accompanied by extracapillary proliferation of Bowman's capsule (crescents)[53] (Fig. 68-5). Depending on the duration and extent of renal injury, varying degrees of glomerular fibrosis and sclerosis may be seen.[36] Vasculitis affecting the kidney often involves only the glomerular capillaries; macroscopic arteritis is seldom apparent.[85] When the lung is involved, the histopathology is nonspecific, demonstrating only capillaritis and intra-alveolar hemorrhage.[1,13,51] Immune deposits are absent.

Clinical features of ANCA-associated DAH syndromes overlap. Striking elevations in ESR and CRP may be observed in all the syndromes, particularly when disseminated vasculitis is present.[1] Anemia and leukocytosis are common. Marked eosinophilia is characteristic of EGPA[17,104] but is not a feature of MPA[1,13] or GPA.[87] Extrapulmonary and extrarenal manifestations suggesting small-vessel vasculitis (e.g., palpable purpura, leukocytoclastic vasculitis, mononeuritis multiplex, arthralgias or arthritis, ocular disease, sinusitis) may direct biopsies at these sites. Histologic features of granulomatous vasculitis are consistent with GPA[16] or EGPA,[17] whereas granulomas are lacking in MPA.[9,13,85] Chest radiographic features may discriminate granulomatous vasculitides from MPA. In GPA (and, less commonly, in EGPA), focal nodular or cavitary mass lesions may be seen.[16,87] These are not found in MPA.[9,13] The diagnosis of EGPA can usually be readily established by a pronounced eosinophilic component in the blood or in extravascular sites.[17,104] However, discriminating GPA from MPA may be difficult or impossible as small-vessel vasculitis is common to both disorders.

By definition, GPA is associated with concomitant granulomatous inflammation typically, but not invariably involving the upper and lower respiratory tracts.[16,87] The latter may lead to the highly distinctive features attributed to GPA including sinusitis, otitis media, nasal or laryngotracheal ulcerations, subglottic stenosis, and cavitary pulmonary nodules.[87]

Characteristics of ANCA

The identification of circulating antibodies directed against cytoplasmic components of neutrophils and monocytes (i.e., ANCA) represented a major advance in the classification and understanding of vasculitis.[84,86] Using ethanol-fixed granulocytes incubated with patient serum, two distinct patterns of ANCA are identified by IF techniques: cytoplasmic (c-ANCA) and perinuclear (p-ANCA) (Fig. 68-9).

The p-ANCA pattern is an artifact of fixation causing movement of the target antigens to a perinuclear location. These IF patterns reflect distinct antigenic specificities. The antibody responsible for c-ANCA is directed against proteinase 3 (PR-3),[84] whereas the p-ANCA pattern is usually due to an antibody to myeloperoxidase (MPO).[84] MPO-ANCA is usually associated with small-vessel vasculitis, but multiple p-ANCA antibodies directed against a variety of antigens (e.g., cathepsin G, lactoferrin, elastin) may be seen in nonvasculitic inflammatory disorders, including CTD and inflammatory bowel or liver disease.[86] Therefore, while c-ANCA is more than 90% specific for small-vessel vasculitis, p-ANCA is nonspecific. In untreated GPA, circulating c-ANCA (PR3-ANCA) is detected in more than 70% of patients; the incidence is lower (40%–65%) in patients with limited disease (e.g., involvement confined to the upper respiratory tract).[16] By contrast, p-ANCA (MPO-ANCA) is rarely found in GPA. Circulating ANCAs are present in more than 70% of patients with MPA[13,51,100] and 30% to 70% of patients with EGPA.[17,19] In MPA, either c-ANCA or MPO-ANCA may be present, but MPO is more common.[13,84,100] Individual patients almost never have both c-ANCA and p-ANCA.

The antigenic specificities of ANCA (i.e., PR3 or MPO) may provide clues to the nature of the underlying disorder and may assist in categorizing the type of disease, but overlap exists.[84,86] Biopsies are important to differentiate the nature of the underlying vasculitic disorder. For example, patients with c-ANCA and small-vessel vasculitis may be misclassified as MPA if clinically inapparent areas of granulomatous inflammation are overlooked. For clinical purposes, distinguishing GPA from MPA is not critical, because therapy and management are similar.[16,90] Circulating p-ANCA (MPO) or c-ANCA (PR3) are present in more than 70% of patients with pauci-immune necrotizing GN (renal vasculitis).[38,84,86,105] ANCA-negative patients usually have disease limited to the kidney. Nearly all patients with concomitant DAH have circulating ANCA.[1] Indeed, a negative ANCA provides strong evidence against vasculitis as the cause of DAH and GN. When applied to patients with RPGN, a positive ANCA almost invariably predicts pauci-immune necrotizing GN.[38] In the setting of clinical, laboratory, and radiologic features that are highly suggestive of DAH and RPGN, a positive c-ANCA or MPO-ANCA, together with a negative anti-GBM and ANA assay, is virtually diagnostic of systemic vasculitis (e.g., GPA or MPA). Similarly, a positive ANCA (usually MPO-ANCA) is sufficient to diagnose lung-limited MPA, provided the clinical presentation is typical of DAH and nonimmune causes of DAH have been excluded. Most patients previously diagnosed as having idiopathic pulmonary hemosiderosis (IPH) likely had lung-limited MPA or ANCA-associated pulmonary capillaritis.

Problems with using serum ANCA to diagnose vasculitis arise when the clinical presentation is ambiguous. The low incidence of vasculitis in the general population dictates that the positive predictive value of ANCA will be low when applied indiscriminately. Routine assay of serum ANCA in patients with nonspecific respiratory complaints yields a high rate of false-positive results. Given the risks of immunosuppressive therapy, misinterpretation of ANCA may lead to devastating consequences. Accordingly, results of serum ANCA assays must be interpreted in light of the entire clinical picture.

Anti-GBM disease and vasculitis have traditionally been viewed as distinct clinicopathologic entities. However, up to 30% of patients with anti-GBM disease (as evidenced by anti-GBM antibody in serum and linear deposits of IgG in kidney biopsy) also have serum MPO-ANCA.[21,24,51,52,68] The coexistence of ANCA and anti-GBM

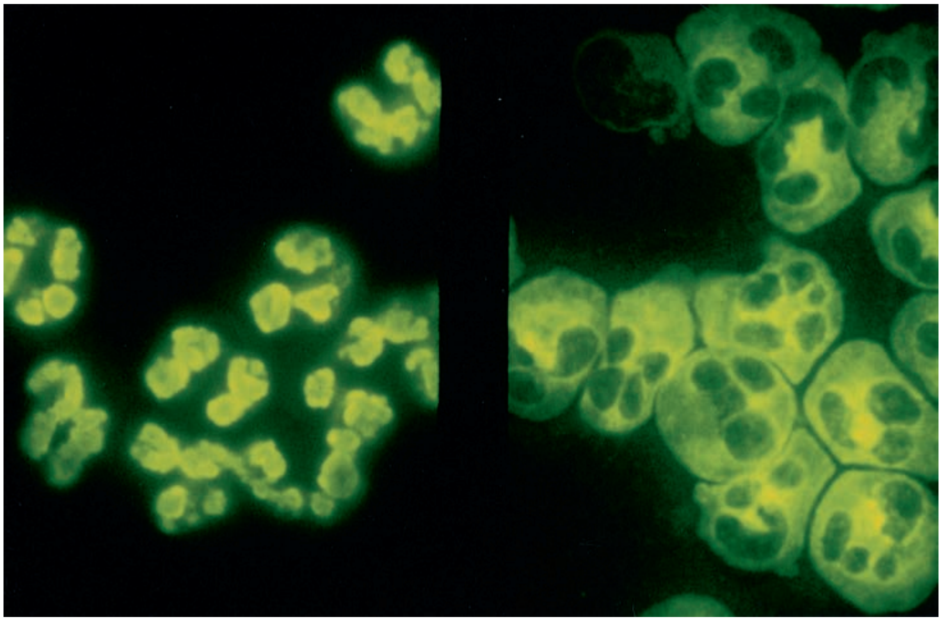

Figure 68-9 Indirect immunofluorescent stains demonstrating two distinct types of antineutrophil antibodies. On the left panel, note the perinuclear pattern of immunofluorescence characteristic of p-ANCA (myeloperoxidase epitope). On the right panel, a coarse granular pattern of immunofluorescence within the cytoplasm is evident, characteristic of c-ANCA (proteinase-3 epitope).

antibodies is almost certainly not a chance occurrence, given the rarity of both antibodies in the general population.[68] It is possible that ANCA initiates vascular injury, and anti-GBM antibody then forms in response to the damaged basement membrane. ANCA antibodies almost certainly mediate vascular damage.[84,86,88,105] Sera from patients with either C-ANCA or P-ANCA induce neutrophils to undergo a respiratory burst with release of reactive oxygen species and proteolytic enzymes.[84] Cytokine-primed neutrophils are stimulated by ANCA to damage human endothelial cells in vitro.[84] These observations, together with correlations of ANCA titer with clinical disease in humans (although imperfect), suggest that ANCAs are not innocent markers of vasculitis but play a crucial role in mediating vessel injury.[84,86,105]

Therapy

Therapy of DAH due to AAV depends on the underlying disorder and the extent and severity of symptoms. Irrespective of etiology, the most immediate concern in patients with severe immune DAH is to control intrapulmonary bleeding, which may be fatal. Besides general supportive measures, high-dose, IV "pulse" MP (followed by a tapering regimen of CS) should be given. For GPA or MPA, CYC or RTX should be initiated. As will be discussed later, the role of RTX to treat EGPA has not been clarified.

Therapeutic Plasma Exchange (TPE) TPE has been used, with anecdotal successes, for AAV with severe renal insufficiency[106–111] or DAH[8,99,106] but is not considered standard therapy. Because ANCAs likely play a pivotal role in mediating tissue injury, TPE may be beneficial in *selected* patients (particularly those with DAH[106] or severe renal failure, i.e., serum creatinine >4 mg/dL[77,112] or dialysis dependency[107,109,111,113]). In 2007, Jayne et al. reported 137 patients with AAV and severe renal failure (serum creatinine >5.8 mg/dL).[112] Overall, 95 (69.3%) had MPA and 42 (30.7%) had GPA. A total of 70 patients were randomized to receive 7 plasma exchanges; 67 patients were randomized to receive IV pulse MP (3000 mg). Both groups received oral CYC and oral prednisolone. The primary endpoint was dialysis independence at 3 months. Secondary endpoints included renal and patient survival at 1 year and severe adverse event rates. At 3 months, 48 of 70 (69%) receiving TPE were alive and independent of dialysis compared with 33 of 67 (49%) treated with IV MP ($p = 0.02$). Furthermore, only 19% of patients receiving TPE progressed to ESRD by 12 months compared to 43% among those receiving IV MP. Patient survival and severe adverse event rates at 1 year were similar (73% and 50%, respectively) in the TPE group compared with 76% and 48%, respectively, in the IV MP group. Thus, TPE was associated with a higher rate of renal recovery in patients with AAV when compared with IV MP while patient survival and severe adverse event rates were similar in both groups.[112]

Despite the apparent benefit of TPE in that 2007 publication,[112] a subsequent multicenter, global clinical trial randomized 682 AAV patients with renal insufficiency (creatinine clearance <50 mL/min/m^2) *and/or* DAH to TPE (7 exchanges within 14 days) or no TPE.[60] All patients received induction therapy with either CYC or RTX. Additionally, cases were randomized to reduced dose oral CS or "standard"-dose CS. Cases were followed for up to 7 years, and composite outcome (death from any cause or ESRD) was assessed. Rates of death or ESRD were 100/352 (28.4%) in the TPE group and 109/352 (31.0%) among controls ($p = 0.27$). Additionally, death or ESRD developed in 92/330 (27.9%) in the reduced-dose CS group compared with 83/325 (25.5%) receiving standard-dose CS, which met criteria for noninferiority. Serious infections at 1 year were less frequent in the low-dose CS group compared with controls (incidence ratio, 0.69). These data cast doubt on the role of TPE for patients with *autoimmune* DAH (other than anti-GBM disease) and renal insufficiency. However, limitations of that important study should be emphasized. Severe DAH (defined as O_2 saturation $\leq 85\%$ on room air or requiring MV) was present in fewer than 9% of cases, and only 20% required dialysis on study entry.[60] At 1-year follow-up, there was a nonsignificant advantage with TPE (hazard ratio [HR], 0.77).[60] Importantly, TPE was not associated with increased adverse events at 1 year. While this study[60] suggests that *routine* use of TPE is not appropriate in most cases of AAV with renal insufficiency, TPE may have a role in *selected* cases (e.g., those with markedly elevated ANCA titers, renal insufficiency *approaching* need for dialysis, or severe DAH).[65] When TPE is used to treat ANCA-associated DAH, it may be preferable to use an apparatus that efficiently removes both IgM and IgG, because of the reported association of IgM-ANCA and DAH.[113]

Recent therapeutic options for AAV include (1) combining RTX and CS with short-course low-dose oral CYC; (2) combining RTX and CS with short-course low-dose IV pulse CYC, followed by maintenance AZA; (3) combining CYC or RTX plus either avacopan (an oral C5a receptor inhibitor) and low-dose CS versus standard-dose CS. Additional strategies for patients failing or intolerant of conventional therapies include high-dose intermittent IV IgG.[114] The mechanism of action is uncertain but may involve binding of ANCA idiotype by anti-idiotype antibodies in the IV IgG preparation.[114]

Patient Follow-up and Assessing Response to Therapy

The role of serial ANCA determinations in following patients with vasculitis is controversial. We do not base therapeutic decisions on the ANCA titer alone. However, a rising titer should alert the clinician to the possibility of disease exacerbation, and clinical follow-up should be intensified. Serial ANCA titers may help differentiate disease relapse from nonimmune causes of pulmonary infiltrates. However, ANCA titers do not obviate the need to aggressively evaluate patients with vasculitis presenting with a new pulmonary process while receiving immunosuppressive therapy.

■ Eosinophilic Granulomatosis with Polyangiitis (EGPA)

Formerly known as Churg-Strauss Syndrome, or allergic angiitis and granulomatosis, EGPA is a rare, small-vessel vasculitis associated with a prominent allergic component, asthma, and eosinophils in blood or involved tissues.[17] EGPA involves capillaries, venules, and arterioles.[17] Granulomas, eosinophils, and palisading histiocytes in extravascular tissues are hallmarks of the disorder[17,104] and distinguish EGPA from other vasculitides.[17,115,116] The annual incidence of EGPA has been estimated at 0.6 to 6.8 cases per million.[17,20,70,117]

In the classic form of EGPA, vasculitis develops after a several-year history of atopy or asthma.[104] Pulmonary involvement is nearly invariably present.[17,104] Asthma is present in 96% to 100%, and focal infiltrates on chest radiographs are present in 30% to 70% of cases.[17,104] DAH is a rare complication of EGPA. In a French series of 112 patients with EGPA, moderate DAH was observed in 3 of 43 ANCA-positive patients and in 5 of 69 ANCA-negative patients.[118] DAH was cited in only 1 of 32 patients in a Spanish series[119] and 1 of 19 in an Italian series[120] of EGPA. Severe DAH has thus only rarely been reported in EGPA.[17,121] Extrapulmonary manifestations of EGPA include mononeuritis multiplex (63%–93%); skin (50%–78%); cardiac (16%–56%); kidney (16%–49%); and gastrointestinal (GI) tract (17%–58%) involvement.[17,115] Factors associated with a worse prognosis include cardiac or GI tract involvement, renal insufficiency, and age >65 years.[17,122]

ESR, CRP, and blood eosinophil count are elevated in more than 80% of patients during the acute phase of vasculitis or exacerbations.[17,19,104,122] Circulating ANCAs (primarily p-ANCA) have been detected in 40% of patients with EGPA.[17,118,123,124] Interestingly, the presence of ANCA was associated with a higher incidence of renal involvement and DAH, but a lower frequency of cardiac involvement.[123]

CS (alone or combined with IA) have been the mainstay of therapy for EGPA.[17,19] CS achieve remissions in more than 80% of patients with EGPA and are first-line therapy for mild to moderate cases.[17,125] Oral or pulse CYC (or other IA such as AZA, MTX, or mycophenolate mofetil) have been added for severe or multisystemic disease or CS-recalcitrant cases or when unfavorable prognostic factors are present.[17,19,122,125,126] Data regarding RTX to treat EGPA are scant and insufficient to recommend RTX for this disorder. TPE is rarely used to treat GPA, but theoretically it may be useful in ANCA-positive CSS patients with severe pulmonary–renal syndrome failing CS and CYC.[17,106,112]

■ Connective Tissue Disorders

Alveolar hemorrhage may complicate connective tissue disorders, including systemic lupus erythematosus, among others.

Systemic Lupus Erythematosus (SLE)

DAH is a rare, but potentially catastrophic, complication of SLE, with mortality rates as high as 62%.[26–28,127–132] DAH complicating SLE is almost invariably accompanied by other manifestations of active SLE.[26,127,128,130–133] GN is present in more than 90% of cases of DAH complicating SLE.[26,127,128] Diffuse, bilateral alveolar infiltrates, dyspnea, and hypoxemia are characteristic (Fig. 68-10). Hemoptysis is noted in a minority of patients at presentation but usually develops during the course of the disease.[26,128,133] The diffuse pulmonary infiltrates must be differentiated from other pulmonary complications of SLE,[134,135] including lupus pneumonitis, opportunistic infections, congestive heart failure, uremia, or pulmonary embolism.

The risk of surgical lung biopsy is substantial in critically ill patients with fulminant DAH, and biopsy is contraindicated. In addition, as with other immune DAH syndromes, histopathologic features of DAH complicating SLE are nonspecific. The dominant feature is intra-alveolar hemorrhage and capillaritis, without macroscopic necrosis.[2,26] The small-vessel necrotizing vasculitis rarely extends to arterioles and small muscular arteries in addition to capillaries. Granular deposits of IgG or C3 (consistent with immune complexes) have been found in up to 50% of cases of DAH complicating SLE.[26,136] Provided that clinical features are consistent, the diagnosis of DAH can be established by flexible bronchoscopy with BAL. The presence of gross blood in the airways or serosanguineous BAL fluid, large numbers of hemosiderin-laden macrophages,[2] absence of purulent sputum, and lack of infectious organisms by appropriate stains strongly support the diagnosis of autoimmune DAH and justify institution of therapy. Transbronchial lung biopsies should not be done in acutely ill patients with severe DAH and respiratory failure. In this context, BAL alone is adequate, primarily to exclude local or infectious causes of bleeding.

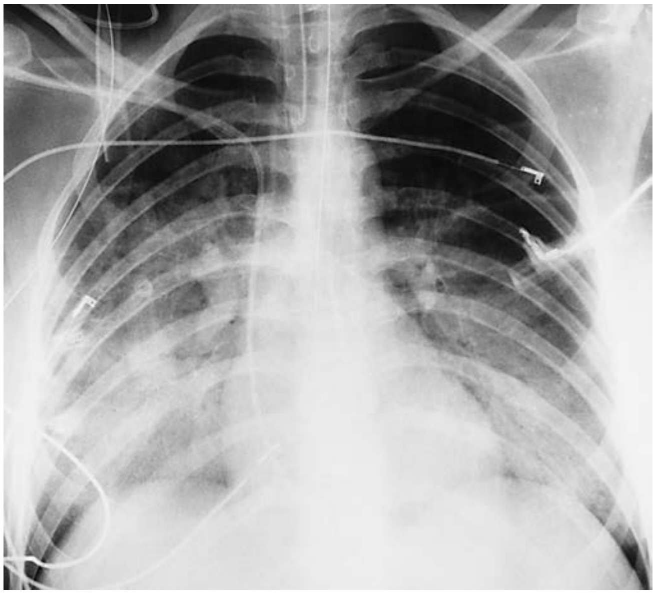

Figure 68-10 Systemic lupus erythematosus (SLE). Posterior–anterior chest radiograph reveals extensive bilateral alveolar infiltrates in a 22-year-old woman with SLE, hemoptysis, and anemia.

Mortality rates of SLE-associated DAH are high, even with aggressive therapy with CS and CYC. In one large, tertiary care center, 19 episodes of DAH were observed among 15 patients with SLE over a 10-year period, accounting for 3.7% of hospitalizations for complications of SLE.[26] The majority (66%) were women, with a median age of 27 years. The onset was often abrupt (<3 days in 12 episodes) and was the presenting feature of SLE in 3 cases. Lupus nephritis was present in 14 of 15 cases. Hemoptysis was present in only 42% at presentation but developed in all during the hospitalization. Lung tissue (available in 10 cases) showed capillaritis in 8, and overall mortality was 53%. Factors associated with heightened mortality included need for MV (62% vs. 0%); infection (78% vs. 20%); and treatment with CYC during that hospitalization (70% vs. 20%), likely reflecting increased infection risk from prior outpatient treatment with CYC for lupus nephritis.

Martinez-Martinez reported 29 episodes of DAH in 22 SLE patients, with 15 deaths.[128] In 4 cases, the diagnosis was made at autopsy. Thrombocytopenia, renal failure, the need for MV, and high APACHE II scores were associated with increased mortality.

Canas et al. reported 7 cases of DAH among 122 SLE patients (5.5%).[133] Five were women with a mean age of 24.3 years. Mean duration of SLE was 15.7 months; in 2 cases, DAH was the presenting feature of SLE. All 7 had evidence for active SLE, including GN in 4. BAL revealed bloody fluid and hemosiderin-laden macrophages in 5 of 7 cases, and 6 patients required MV. All received IV pulse MP and IV pulse CYC; TPE was added in 4 failing pharmacologic therapy. Only one died, suggesting that aggressive therapy including TPE was life-saving.

Columbian investigators reported 17 cases of DAH complicating SLE who required admission to the ICU.[28] Of these, 11 (65%) were women; median age was 28 years. All received IV pulse MP and TPE; 13 (79%) also received IV pulse CYC. Five (29%) died during the hospital stay. Factors associated with increased mortality included need for MV and vasoactive/inotropic support.

Korean investigators reported 21 cases of DAH among 1521 SLE patients (1.4%) admitted to the hospital;[127] 13 died (62%). Independent risk factors for DAH included SLE disease activity score >10 ($p = 0.029$) and neuropsychiatric SLE ($p = 0.002$). Factors associated with increased mortality included need for MV and presence of infection.

The prognosis is worse in juvenile-onset (jSLE) compared with adult-onset (aSLE) SLE.[129] DAH occurred in 13/263 (4.9%) cases of jSLE and 15/1522 (1.0%) cases of aSLE. MV was required in 85% of jSLE compared with 47% in adults ($p = 0.055$); mortality rates were higher in jSLE (69% vs. 13%; $p = 0.006$). Treatment regimens were similar in both groups.

In another study of 847 cases of jSLE, DAH developed in 19 (2.2%).[132] All 19 had cough, dyspnea, hypoxemia, and diffuse infiltrates on chest x-ray or CT. MV was required in 14 (74%); 9 (47%) died. These patients with DAH were compared with 76 jSLE cases *without* DAH with the same disease duration (3 [1–151] vs. 4 [1–151] months, respectively). Compared with the jSLE controls *without* DAH, 19 cases of jSLE with DAH showed higher frequencies of constitutional involvement (74% vs. 10%; $p < 0.0001$), serositis (63% vs. 6%, $p < 0.0001$), and sepsis (53% vs. 9%, $p < 0.0001$).[132] Further, median disease activity score (SLEDAI-2 K) was significantly higher in jSLE patients with DAH compared to controls *without* DAH (18 [5–40] vs. 6 [0–44]; $p < 0.0001$). Further, jSLE patients with DAH had a higher incidence of thrombocytopenia (53% vs. 12%; $p < 0.0001$), and the use of IV MP (95% vs. 16%; $p < 0.0001$) and IV CYC (47% vs. 8%; $p < 0.0001$) was significantly higher in DAH patients.[132]

Xu et al. performed a meta-analysis of five studies assessing risk factors for DAH among patients with SLE.[131] The following factors were associated with DAH: neuropsychiatric involvement (OR, 4.32; $p = 0.002$); nephritis (OR, 3.15; $p = 0.001$); serositis (OR, 6.03; $p = 0.015$); and lower serum C3, C4, and hemoglobin.

Kim et al.[130] reported 47 SLE patients with diffuse lung infiltrates, of whom 24 (51%) had DAH. Factors associated with DAH included lower hemoglobin (OR, 3.46; $p < 0.01$); low serum C4 (OR, 1.21; $p = 0.02$); hypoxemia (OR, 23.1; $p = 0.03$); and need for MV (OR, 64.6; $p = 0.02$).

Due to the rarity of SLE-associated DAH, prospective, controlled trials evaluating therapy have not been performed. As with other causes of immune DAH, IV pulse MP (500–1000 mg daily for 3 days), followed by gradual CS taper[26,129,133] and CYC (IV pulse or oral) have been the mainstay of therapy.[128,129,133,137] RTX has been efficacious in anecdotal cases of SLE-associated DAH,[137–140] but data are sparse. The role of TPE has not been elucidated, but anecdotal successes with TPE have been cited for severe DAH complicating SLE.[26,113,129,133,141,142]

Other Connective Tissue Diseases

Anecdotal reports of DAH, with or without capillaritis, have been described in association with rheumatoid arthritis,[143] scleroderma,[144] mixed-connective tissue disease,[143] polymyositis,[145] dermatomyositis,[146] antiphospholipid antibody syndrome,[147–150] Henoch-Schönlein syndrome,[151,152] and Behçet's disease.[81,153] The clinical spectrum ranges from minimal hemoptysis to life-threatening respiratory failure. In addition to capillaritis and DAH, additional histopathologic features on lung biopsies include vasculitis of small and medium muscular pulmonary arteries, DAD, and organizing pneumonia. In view of the rarity of DAH complicating these diverse CTDs and vasculitic syndromes, data regarding therapy are limited. IV pulse MP is advised as initial treatment. In patients with fulminant or CS-recalcitrant disease, CYC, alone or combined with TPE,[113,144] should be added.

■ Alveolar Hemorrhage in Immunocompromised Hosts

DAH may occur in immunocompromised patients.[47,154] In this setting, it may reflect injury to pulmonary endothelial or epithelial cells (secondary to chemotherapy or radiation toxicity), thrombocytopenia (secondary to bone marrow toxicity), pulmonary edema, pulmonary malignancies, and diverse infectious and nonspecific interstitial pneumonias.[154] The incidence of DAH in severely immunocompromised hosts with hematologic malignancies or bone marrow transplants has varied from 11% to 64%.[43,154] The variable frequency in large part is due to differing diagnostic criteria for the diagnosis of DAH. Subclinical alveolar hemorrhage (as evidenced by increased numbers of hemosiderin-laden macrophages in BAL) occurs in up to one-third of immunocompromised hosts with pulmonary infiltrates and may reflect pulmonary endothelial or epithelial injury from diverse causes.[47] Nonimmune causes of DAH in this patient population include coagulopathy, thrombocytopenia or platelet dysfunction, renal failure, congestive heart failure, bronchopulmonary Kaposi's sarcoma, and diverse infections.[47,48]

Alveolar Hemorrhage Complicating Bone Marrow Transplantation

DAH occurs in approximately 5% (range, 2%–31%) of hematopoietic stem cell transplant (HSCT) or bone marrow transplant (BMT) recipients receiving pretransplant conditioning with high-dose chemotherapy or radiation therapy.[43,44,155–159] Opportunistic infections or thrombocytopenia account for some cases of DAH,[44,157] but a distinct syndrome of DAH in this population unrelated to infection is well accepted.[154,155] The incidence of DAH is similar among autologous and allogeneic HSCT recipients.[43,155,158]

Risk factors for DAH include age >40 years;[156,158] myeloablative conditioning;[43,156,158] thoracic[160] or total body irradiation;[43,159,161] acute severe graft-versus-host disease (GVHD);[156,161] severe oral mucositis;[162] renal failure;[43] airway inflammation or increased proportions of bronchial neutrophils and eosinophils;[163] and leukocyte recovery.[43,163] Thrombocytopenia or coagulopathy do not predict DAH.[43,160]

DAH usually develops within 10 to 40 days after BMT but may develop earlier or later.[155,159–161] DAH developed in ~5% of 1228 allogeneic HSCT recipients at the University of Minnesota from 2008 to 2015 at a median of 30 days post-transplant.[159] The incidence was increased in recipients of umbilical cord blood (UCB) transplants compared with peripheral blood (PB) or bone marrow (BM) grafts (HR, 2.08; $p = 0.01$). Multivariate analysis demonstrated that delayed neutrophil engraftment or primary graft failure was associated with increased incidence of DAH following PB or BM transplant (HR, 5.51; $p = 0.02$) and delayed platelet engraftment was associated with increased incidence of DAH among UCB recipients (HR, 6.96; $p < 0.05$). Total body radiation was a risk factor for DAH in PB, BM, and UCB transplant recipients (HR, 1.8; $p = 0.l05$). DAH was associated with increased 6-month transplant-related mortality (HR, 6.09; $p < 0.01$) and lower 2-year survival (HR, 4.2) in all graft source groups. Case reports of DAH developing immediately following autologous BMT suggest that components within the transfusion (e.g., dimethyl sulfoxide [DMSO] for cryopreservation of blood stem cells) may mediate acute lung injury in some cases.[164]

DAH typically manifests as progressive dyspnea, hypoxemia, and respiratory failure.[43,156,158] Even with extensive DAH, hemoptysis is uncommon (<20%).[155,158,163] Chest radiographs *initially* demonstrate predominantly interstitial opacities, which evolve to diffuse alveolar opacities, with a confluent alveolar pattern involving all lobes. Serosanguineous or frankly bloody BAL fluid,[155,156,158] with negative stains for infectious organisms, support the diagnosis of DAH. Lung biopsies or necropsies typically reveal histologic features of both DAD and DAH.[157,163,165] However, the risk of lung biopsy is excessive in critically ill patients, many of whom are thrombocytopenic.[158] Hence the diagnosis is made by clinical, radiographic, and BAL findings.[155,158]

The clinical course of DAH is variable, but severe respiratory failure requiring MV is common.[155,162] Mortality rates in patients with DAH are high (60-day mortality ranging from 48% to 84%).[44,155,156,162] In one study, hospital mortality was lower among autologous (28%) compared with allogeneic (70%) SCT recipients; further, mortality was lower (32%) in early-onset DAH (within 30 days of transplant) compared with 70% mortality for late-onset DAH.[155] Secondary infections are serious and potentially lethal.[44,154,156,157]

Multiple mechanisms may mediate DAH in this patient population. Diffuse injury to the pulmonary microvasculature, secondary to chemotherapy or radiation therapy, is coupled with a heightened inflammatory response in the airways.[43] Bleeding may be amplified by a precipitating factor such as coagulopathy, pulmonary edema, GVHD, or infections. DAD, a pathologic hallmark seen in toxic lung injury from chemotherapy, radiation therapy, or viral infections, is frequently observed in lung biopsies or necropsies in BMT recipients with DAH.[155] An association between microangiopathy and DAH in patients receiving BMT for hematologic malignancies has been cited.[166] Neutrophils and other inflammatory cells likely play important roles in the pathogenesis of DAH. The onset of DAH frequently coincides with marrow recovery and reappearance of neutrophils within the circulation or BAL fluid. Influx of neutrophils may promote lung injury by release of oxygen radicals, proteases, and other inflammatory mediators.[43,163] Hematopoietic growth factors (e.g., granulocyte colony–stimulating factor) may exacerbate alveolar damage and capillary leakage by increasing neutrophil influx into the lungs.[43]

High-dose pulse IV CS is considered the standard of care for DAH,[43,44,155,157] but RCTs are lacking and a survival benefit has not been established. Unfortunately, DAH or bloody BAL fluid may be seen in infectious causes of pneumonia (particularly due to cytomegalovirus [CMV] or *Aspergillus* spp),[158] and high-dose CS could be disastrous in these circumstances. Infectious etiologies must thus be rigorously excluded. Among patients who respond favorably to CS, the dose can be gradually tapered over 2 to 6 weeks.[43,155] A more prolonged course is appropriate for patients with GVHD or other complications requiring long-term CS therapy. Anecdotal response to recombinant factor VIIa was cited in one allogeneic SCT recipient with DAH.[167]

Alveolar Hemorrhage Complicating HIV Infection

DAH can complicate human immunodeficiency virus (HIV) infection. The incidence and clinical significance of DAH is not clear, as additional pulmonary processes (e.g., opportunistic infections,[168] Kaposi's sarcoma[169]) are usually present.[48] Subclinical episodes of AH are common, as studies in HIV-infected patients with pulmonary infiltrates detected more than 20% hemosiderin-laden macrophages in BAL fluid in 15% to 44% of patients.[47,48] In one study of 203 HIV-infected patients with pulmonary symptoms who underwent BAL, AH was detected in 73 (36%); however, AH was severe in only 8 patients, and AH did not affect survival.[48] Thrombocytopenia, coagulopathy, renal failure, hydrostatic pulmonary edema, CMV pneumonia, and Kaposi's sarcoma were more frequent in patients with AH compared to HIV-infected controls *without* AH.[48] Pulmonary capillaritis has been cited in occasional patients, most of whom had concomitant opportunistic infections. CMV pneumonia has been implicated as a cause of DAH in HIV-infected patients.[168] CMV exhibits tropism for endothelial cells, and CMV may induce vascular injury or thrombotic microangiopathy. Antiviral therapy (e.g., ganciclovir, valganciclovir) may be curative for CMV-associated DAH. The incidence and appropriate therapy of DAH of unknown etiology in the setting of HIV infection has not been well defined.

■ Alveolar Hemorrhage Due to Exogenous Agents

Certain exogenous agents or drugs[31,51] (e.g., trimellitic anhydride,[170] isocyanates,[171] D-penicillamine,[172] cocaine,[32] diphenylhydantoin,[173] propylthiouracil,[174] hydralazine,[175] sulfasalazine,[175] allopurinol,[49,175] all-*trans*-retinoic acid [ATRA],[176] minocycline[177]) are rare causes of DAH. An exhaustive list of drugs capable of causing DAH is available at *www.pneumotox.com*. Circulating ANCAs, GN, and DAH have been linked with some agents (particularly D-penicillamine,[172] hydralazine,[178] propylthiouracil,[174] methimazole, and carbimazole[179]). Lung biopsies have rarely been performed in these cases of DAH. However, pulmonary capillaritis (without immune deposits) is the most common finding.[31,51]

ATRA, a therapeutic agent for acute promyelocytic leukemia, may be associated with "retinoic acid syndrome," characterized by fever, thrombosis, pulmonary infiltrates, and DAH.[176] The onset is 2 to 21 days after initiation of treatment. In this circumstance, ATRA is often continued, but high-dose IV CS should be administered.

Propylthiouracil can cause a systemic small vessel vasculitis with necrotizing GN, leukocytoclastic vasculitis, ANCA, and DAH secondary to pulmonary capillaritis.[174,175] Withdrawal of the drug may be associated with resolution of the disease, but CS or IA are indicated in patients with severe DAH or renal failure. A variety of chemotherapeutic agents (e.g., bis[chloroethyl] nitrosourea [BCNU], carmustine, CYC, MTX, mitomycin C, bleomycin, busulfan) may cause lung injury and fibrosis.[31,180] In some cases, DAH may result from epithelial injury and injury to the alveolar capillary basement membranes.[31] In this context, fatality rates are high (>50%).[31,180] High-dose CS are recommended, but efficacy is uncertain.

Trimellitic anhydride (TMA), a chemical used in manufacturing plastics and epoxy resins, may elicit DAH and anemia.[170,171] Most patients with DAH secondary to TMA recover within a few days following removal from the offending environment. An immune mechanism is likely, as circulating IgG antibodies against trimellitic protein were found in some patients with DAH, suggesting that TMA acts as a hapten.[171] TMA may cause asthma, rhinitis, and hemolytic anemia mediated by IgE antibodies directed against trimellitic protein. Animal models of TMA-induced lung disease also have been developed.[170] Induction of serum antibodies against epitopes of TMA produced acute lung injury in animals, mediated by at least two types of humoral antibodies. It is also possible that TMA may exert a direct toxic effect on alveolar endothelium. This syndrome is exceptionally rare; only sporadic cases have been described. Exposure to isocyanates in spray paint has been linked to occupational asthma and (in a few cases) DAH.[181] The mechanism is likely mediated by high levels of IgE and IgG antibodies against diisocyanates.[171] Thus, exposure to TMA or isocyanates, and possibly other chemicals, can elicit hemorrhagic pneumonitis, likely mediated by circulating antibodies (IgG or IgE) and immune complexes.

Smoking, snorting, or IV "crack" cocaine has been associated with hemoptysis and varying degrees of DAH,[32,182] including rare fatalities. Histopathologic features of cocaine-induced DAH are nonspecific but include DAD, acute or chronic DAH, interstitial pneumonitis/fibrosis, and intra-alveolar edema.[183] The mechanism of DAH is not clear but may relate to direct toxic injury from cocaine or its contaminants, vasospasm, or a combination of both mechanisms. This syndrome typically reverses with cessation of exposure. The frequency of clinically significant DAH associated with inhaled or IV cocaine has not been established.

When drug- or hapten-induced DAH is suspected, immediate avoidance of the implicated agent or drug is essential. For acute or severe cases, a brief course of high-dose CS is warranted. TPE or IA may be considered for fulminant cases refractory to CS, but data supporting their use are lacking.

Finally, coagulopathies, severe thrombocytopenia, or the use of anticoagulants, thrombolytic agents, or platelet inhibitors may rarely cause DAH.[184–186] In this context, the histology is "bland," without evidence for capillaritis or acute inflammation.

■ Alveolar Hemorrhage Due to Molds

Acute, life-threatening DAH in infants identified fungal contamination as the etiology[187,188] after exposure to *Stachybotrys chartarum* and other toxigenic fungi.[187] *Stachybotrys chartarum* produces several classes of toxins including hemolysins, proteinases, macrocyclic trichothecenes, phenylspirodrimanes, and others.[187,189] Acute respiratory distress, progressing to respiratory failure requiring MV, may occur.[187] High-dose IV CS are warranted for acute DAH. Long-term management mandates removal of infants from the residential environment to avoid relapse.[187,188] This syndrome has rarely been reported in adults, but must be considered in water-damaged homes or environments where mold/fungal contamination exists.[188,189]

■ Idiopathic Pulmonary Hemosiderosis (IPH)

IPH is an exceptionally rare cause of DAH that occurs primarily in infants and children.[190–193] The estimated incidence is 0.2 to 1.2 cases per million.[40,194] Many children with IPH have a history of milk or gluten sensitivity.[195] A subset of adults with celiac sprue manifest IPH,[196] which may respond to elimination of gluten from the diet.[197] Clinical features of IPH are similar to immune causes of DAH, but extrapulmonary or renal involvement is lacking.[190] Serum or tissue antibodies (e.g., ANCA, immune complexes, anti-GBM) are absent. A diagnosis of IPH can be made *only* when other specific causes of DAH have been *reliably* excluded. Most early series of IPH, published in the 1960s and 1970s, antedated the availability of serologies and immunohistochemical assays (e.g., ANCA, anti-GBM antibody).[198] It is likely that most cases formerly diagnosed as IPH in adults had AAV or underlying CTD.

The onset of the disease is typically in infants and young children (<5 years old).[190,191] The clinical course of IPH is variable, but recurrent episodes of DAH over several years are characteristic.[190,193,199] Spontaneous remissions without long-term sequelae have been cited in up to 25% of cases.[193] Sequelae of recurrent episodes of DAH include pulmonary fibrosis, progressive respiratory failure, and cor pulmonale.[190,193,199] Early studies cited median survival rates of 3 to 6 years,[191,194] but more recent studies suggest a more favorable prognosis, with many patients surviving more than 10 to 15 years.[193,199] During acute episodes, chest radiographs demonstrate bilateral alveolar infiltrates. Following cessation of bleeding, chest radiographs may normalize within 1 to 2 weeks. Reticulonodular infiltrates may be observed as the process is resolving or with recurrent episodes (Fig. 68-11). CT reveals areas of ground-glass opacification, representing foci of AH. Thickening of interlobular septae and honeycombing may be observed in a subset of patients who progress to pulmonary fibrosis.[200] Hemoptysis may be absent, particularly in young children who may be unable to expectorate blood. Iron-deficiency anemia is characteristic and can be profound.[190,193,199,201] Iron deficiency may persist despite normal total body iron stores, because hemosiderin within alveolar macrophages is not available to developing erythrocytes. Siderophages may be found in sputum, BAL fluid, or tracheal or gastric aspirates in patients with recent DAH.[40,193,199] Lung biopsies may reveal fresh areas of AH or patchy interstitial fibrosis and aggregates of hemosiderin-laden macrophages from prior episodes of AH[190,193] (Fig. 68-12).

The pathogenesis of IPH is not known. In children, associations between IPH and cow's milk hypersensitivity, celiac disease,[201] IgA monoclonal gammopathy, autoimmune hemolytic anemia, and autoimmune thyrotoxicosis have been suggested,[193] but a pathogenetic link has not been substantiated. Resolution of pulmonary symptoms following elimination of milk products or gluten from diet[196,201] supports a role for exogenous factors in the pathogenesis in at least some cases. No genetic basis has been found, but clusters within families have been described.[202]

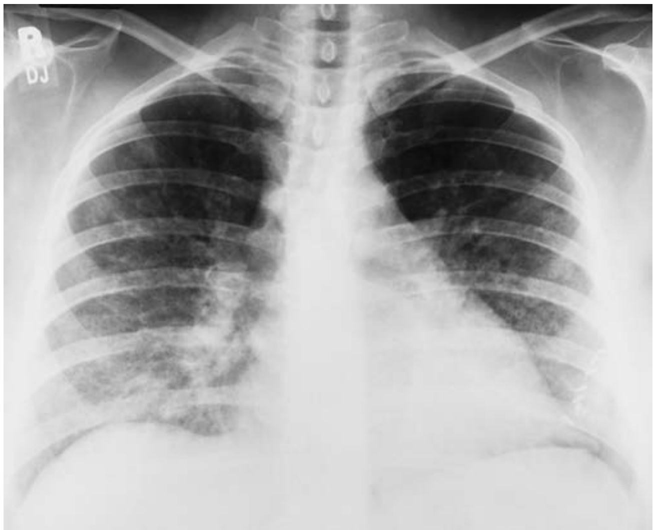

Figure 68-11 Idiopathic pulmonary hemosiderosis (IPH). Posterior–anterior chest radiograph demonstrates bilateral reticulonodular infiltrates in a 28-year-old woman with IPH confirmed 10 years earlier by open lung biopsy.

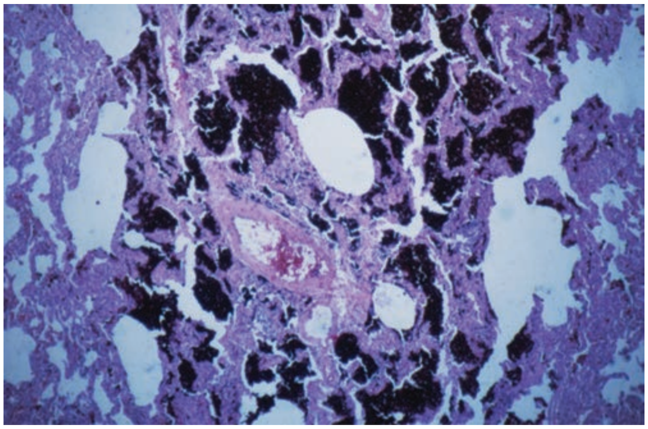

Figure 68-12 Idiopathic pulmonary hemosiderosis (IPH). Photomicrograph demonstrating extensive deposits of hemosiderin within alveolar interstitium (Prussian blue stain).

In view of the rarity of IPH, optimal therapy is not clear. CS are considered the mainstay of therapy,[40,190,192,203] but RCTs have not been done. Because IPH is life-threatening, most physicians treat acute episodes with daily CS and taper to the lowest dose that appears to control the disease. Long-term (and possibly indefinite) therapy may be required to prevent recurrences. Favorable responses have been cited with AZA,[204] CYC,[205] or other IA[199] in patients failing CS. Chronic IA may improve prognosis for patients with CS-recalcitrant disease or patients experiencing repetitive relapses of DAH.[199] In this context, we prefer AZA over CYC given the heightened risk of neoplasia and gonadal toxicities associated with the long-term use of CYC.[206]

CHAPTER 69

Aspiration-Related Pulmonary Disorders

Paul E. Marik

“Captain of the Men of Death”

—William Osler’s reference to pneumonia[1]

INTRODUCTION

Aspiration is defined as the misdirection of oropharyngeal or gastric contents into the larynx and lower respiratory tract.[2] An assortment of pulmonary syndromes may occur following aspiration depending on the quantity and nature of the aspirated material, the chronicity of aspiration, and the nature of the host’s defense mechanisms and the host’s response to the aspirated material. The most important syndromes include “*aspiration pneumonitis*” or Mendelson’s syndrome, which is a chemical pneumonitis caused by the aspiration of gastric contents, and “*aspiration pneumonia*,” an infectious process caused by the aspiration of oropharyngeal secretions colonized by pathogenic bacteria.[2] While there is some overlap between these two syndromes, they are distinct clinical entities.[2] The distinction between these two syndromes is based largely on clinical criteria (Table 69-1). Although gastric biomarkers for aspiration are increasingly available (e.g., pepsin, amylase, lipid-laden macrophages), none has been clinically validated.[3–5] Serum procalcitonin and other inflammatory markers are unable to distinguish aspiration pneumonitis from aspiration pneumonia.[6] The administration of antibiotics is central to the management of aspiration pneumonia, while the treatment of aspiration pneumonitis is largely supportive.[2] In addition to aspiration pneumonitis and aspiration pneumonia, a variety of pulmonary conditions result from chronic recurrent occult aspiration, most notably “*diffuse aspiration bronchiolitis*.”[7] Other aspiration syndromes include airway obstruction, lung abscess, exogenous lipoid pneumonia, chronic interstitial fibrosis, and *Mycobacterium fortuitum* pneumonia. This chapter focuses on the pathophysiology, clinical features, and management of aspiration pneumonitis, aspiration pneumonia, and diffuse aspiration bronchiolitis.

ASPIRATION PNEUMONITIS

Aspiration pneumonitis is best defined as acute lung injury following the aspiration of regurgitated gastric contents.[2] This syndrome occurs in patients with a marked disturbance of consciousness, such as drug overdose, seizures, coma due to acute neurologic insults, massive cerebrovascular accident, following head trauma, and during anesthesia. It is important to emphasize that aspiration pneumonitis occurs only in patients who have a depressed level of consciousness with impairment of airway protective reflexes. In clinical practice, drug overdose is the most common cause of aspiration pneumonitis, occurring in approximately 10% of patients hospitalized following a drug overdosage. Adnet and Baut demonstrated that the risk of aspiration increases with the degree of impairment in consciousness (as measured by the Glasgow Coma Scale).[8] Historically the syndrome most commonly associated with aspiration pneumonitis is Mendelson’s syndrome, reported in 1946 in obstetric patients who aspirated while receiving general anesthesia.[9] Mendelson’s original report consisted of 44,016 nonfasted obstetric patients whom he studied between 1932 and 1945, of whom more than half received an “operative intervention” with ether by mask without endotracheal intubation. He described aspiration in 66 patients (1 in 667). Although several of the patients were critically ill from their aspiration, recovery was usually complete within 24 to 36 h and only 2 patients died (1 in 22,008).

Although aspiration is a widely feared complication of general anesthesia, clinically apparent aspiration in modern anesthesia practice is exceptionally rare, and in healthy patients the overall morbidity and mortality are low (see “Anesthesia and Aspiration,” below). The risk of aspiration is greatly increased in patients intubated emergently in the field, emergency room, or ICU. In these patients, every effort should be made to reduce the risk of aspiration. These efforts include removing dentures, clearing the airway, and in certain circumstances, placing a nasogastric tube to empty

TABLE 69-1 Contrasting Features of Aspiration Pneumonitis and Aspiration Pneumonia

Feature	Aspiration Pneumonitis	Aspiration Pneumonia
Mechanism	Aspiration of sterile gastric contents	Aspiration of colonized oropharyngeal material
Pathophysiologic process	Acute lung injury from acidic and particulate matter	Acute pulmonary inflammatory response to bacteria and bacterial products
Bacteriologic findings	Initially sterile, with subsequent bacterial infection possible	Gram-negative rods, gram-positive cocci, and rarely anaerobic bacteria
Major predisposing factors	Depressed level of consciousness	Dysphagia and gastric dysmotility
Age group affected	Any age group, but usually young persons	Usually elderly persons
Aspiration event	May be witnessed	Usually not witnessed
Typical presentation	Patient with a history of depressed level of consciousness in whom a pulmonary infiltrate and respiratory symptom develop	Institutionalized patient who presents with features of a “community-acquired pneumonia” with an infiltrate in a dependent bronchopulmonary segment
Clinical features	No symptoms or symptoms ranging from a nonproductive cough to tachypnea, bronchospasm, bloody or frothy sputum, and respiratory distress 2 to 5 h after aspiration	Tachypnea, cough, fever, and signs of pneumonia

Reproduced with permission from Marik PE. Aspiration pneumonitis and aspiration pneumonia. N Engl J Med. 2001;344(9):665–671.

the stomach prior to intubation. If there is an immediate risk of airway compromise, endotracheal intubation should be performed prior to placement of a nasogastric tube. However, if the patient is likely to have a full stomach (e.g., from upper GI bleed, small bowel obstruction, ileus), it may be prudent to place a nasogastric tube prior to endotracheal intubation. When intubating emergently, suction equipment must be immediately available and rapid-sequence induction using cricoid pressure should be performed.

■ Pathophysiology

Mendelson emphasized the importance of acid when he showed that unneutralized gastric contents introduced into the lungs of rabbits caused severe pneumonitis indistinguishable from that caused by an equal amount of 0.1 N hydrochloric acid.[9–11] However, if the pH of the vomitus was neutralized before aspiration, the pulmonary injury was minimal. Experimental studies have demonstrated that the severity of lung injury increases significantly with the volume of the aspirate and inversely with its pH, with a pH of less than 2.5 required to cause aspiration pneumonitis.

In experimental models, when acid is instilled into the lungs, a two-phase injury results. The initial injury phase (within 1 h of acid exposure) is primarily due to the acid's direct caustic effects on pulmonary tissue, whereas the second injury phase (beginning at 3–4 h and peaking at 4–6 h postexposure) results from recruited neutrophils.[12,13] The intensity of the alveolar neutrophil infiltration is related to the severity of the acute lung injury. Once localized to the lung, neutrophils play a key role in the development of lung injury through the release of reactive oxygen species (ROS) and proteases that are injurious to the lung.

NADPH oxidase is the major source of ROS in activated neutrophils; other sources of ROS following gastric aspiration include superoxide anion generated by xanthine oxidase.[14] ROS exacerbate acute lung injury through several mechanisms, including direct cellular injury, nuclear factor κB (NF-κB) activation, and activation of other proinflammatory mediators, such as tumor-necrosis factor α (TNF-α) and interleukin 8 (IL-8). The activation of NADPH oxidase in neutrophils is linked to the generation of neutrophil extracellular traps (NETs). NETs are extracellular strands of decondensed (unwound) DNA in complex with histones and neutrophil granule proteins. NETs contain serine proteases and other antimicrobial products that damage the lung.

The stomach contains a variety of other substances in addition to acid. Several experimental studies have demonstrated that aspiration of small, particulate food matter from the stomach may cause severe pulmonary damage, even if the pH of the aspirate is above 2.5.[15,16] These studies suggest that cell recruitment and expression of inflammatory mediators are most pronounced after injury with combined acid and small food particles. These data are supported by findings where the most severe lung injury was observed in patients following aspiration with particulate food matter.[17,18] Gastric acid prevents the growth of bacteria; therefore, the contents of the stomach are normally sterile. Hence, bacterial infection does not play a significant role in the early stages of acute lung injury following aspiration of gastric contents. However, acid aspiration pneumonitis reduces host defenses against infection, increasing the risk of superinfection.[19] The incidence of this complication has, however, not been well studied. Furthermore, experimental models suggest that acid aspiration pneumonitis "primes the lung," making secondary infection more severe.[19,20]

Colonization of the gastric contents by potentially pathogenic organisms may occur when the gastric pH is increased by the use of antacids, histamine 2 (H2) receptor blockers, or proton pump inhibitors. In addition, gastric colonization by Gram-negative bacteria occurs in patients receiving enteral feedings, as well as in patients with gastroparesis and small bowel obstruction. In these circumstances, the pulmonary inflammatory response is likely to result from both bacterial infection and the inflammatory response of the gastric particulate matter.

■ Anesthesia and Aspiration

Aspiration pneumonitis has traditionally been regarded as the major cause of serious anesthetic complications. However, with the recognition of the importance of this complication and that it is largely preventable, the risk of aspiration pneumonitis is modern anesthesia is extremely low. Nevertheless, aspiration pneumonitis is an important perioperative complication and remains the commonest cause of anesthesia-related death. The risk of aspiration with modern anesthesia is reported to be between 2.9 and 4.7 per 10,000 general anesthetics (about 1 in 3000 anesthetics) with a mortality of approximately 1:125,000, accounting for 10% to 30% of all anesthetic deaths.[21,22]

Warner et al. published data from a study of 215,488 anesthetics and observed 67 episodes of aspiration in adults (3.1 per 10,000 patients) undergoing general anesthesia.[11] In a study involving 99,441 patients undergoing nonobstetric anesthesia, perioperative pulmonary aspiration occurred in 14 patients (1 in 7103 procedures).[23] All 14 patients had 1 or more risk factors for aspiration. The Thai Anesthesia Incident Monitoring Study prospectively recorded reports on aspiration from 51 hospitals across Thailand during a 6-month period in 2007.[24] In the study, 28 reports met the definition of pulmonary aspiration (denominator not reported). Most of the incidents occurred in American Society of Anesthesiology (ASA) class 1–2 patients (85.7%), during daytime hours (64.3%), and when the anesthesiologists were in charge (67.9%). A total of 11 incidents (39.3%) occurred during induction, 7 (25%) during maintenance, and 7 (25%) during the emergence phase. All the incidents except 1 (96.4%) were considered human error, and 25 (89.2%) were considered preventable. In all, 13 patients (46.4%) had major physiologic changes, and 10 (35.7%) of them required unplanned ICU admission; 10 patients (35.7%) needed prolonged ventilator support, and 2 (7.14%) died.

The most definitive and extensive review on the risk of airway problems associated with intubation was reported by Cook et al., who summarized the findings of the fourth National Audit Project of the Royal College of Anaesthetists.[25,26] In this 1-year prospective audit, the authors examined the occurrence of serious airway complications in anesthesia, ICUs, and emergency departments of all the National Health Service hospitals in the United Kingdom. The authors found 184 cases that met the inclusion criteria: 133 from anesthesia, 36 from ICUs, and 15 from emergency departments. A concurrent national census of anesthesia activity over a 2-week period was performed to provide denominator data for anesthesia, which indicated 2.9 million anesthetic procedures annually, resulting in a nominal incidence (using the 133 anesthesia events) of 1 serious airway complication per 22,000 anesthetics. In total, 38 deaths were attributable to airway complications, and the death rate was 16 of 133 (12%) in anesthesia, 18 of 36 (50%) in the ICUs, and 4 of 16 (25%) in the emergency departments. Pulmonary aspiration of gastric contents was the commonest cause of death and brain damage. A supraglottic airway was the planned technique in more than 50% of cases associated with death or brain damage. A statistical analysis of the reports suggested that as few as 25% of relevant incidents may have been reported. The authors suggest, therefore, that this audit provides an indication of the lower limit for the incidence of such complications.

Emergency surgery (particularly, trauma and abdominal surgery with delayed gastric emptying) procedures performed at night, inadequate anesthesia, obesity, elderly immobilized patients, and obstructive sleep apnea have been associated with a higher risk of aspiration.[22,27] Obtunded adults and children with known gastroesophageal reflux are more likely to aspirate even without narcotic or sedative impairment of airway reflexes. The factors increasing the

TABLE 69-2 Factors Increasing the Risk of Perioperative Aspiration

Recent eating

Achalasia
Esophageal stricture
Previous gastric bypass surgery
Traumatic brain injury
Cerebral infarction/bleed

risk for aspiration are listed in Table 69-2. Patients who are at risk before surgery are also at increased risk during the postoperative period when immobility, residual effects of anesthetic agents, and narcotics combine to decrease protective airway reflexes.[28–30]

The incidence of aspiration appears higher in obstetric patients, as highlighted by the pioneering study of Mendelsohn.[9] A study from 1973 reported an incidence of 1 in 6000 obstetric patients receiving general anesthesia for vaginal deliveries and 1 in 430 for patients undergoing cesarean section.[31] In more recent studies, an aspiration incidence of 1 in 1547 and 1 in 1431, were described for caesarean section under general anaesthesia;[28,30] a more recent audit showed an incidence of 1 in 900 in women undergoing caesarean section.[29] The risk of pulmonary aspiration is, therefore, at least double or three times as high as in general surgical patients. Pregnant women are at increased risk of aspiration because of gastroesophageal reflux and delay in gastric emptying.[32,33]

Gastroesophageal reflux is common in pregnancy and can be demonstrated even in the absence of symptoms. There is no difference in basal and evoked gastric acid secretion in pregnancy, but there is a reduction in lower esophageal barrier pressure, which is likely to be a progesterone effect present from early pregnancy. The surgical procedure may itself increase aspiration risk through the adoption of lithotomy or Trendelenburg positions or the creation of a pneumoperitoneum.

The laryngeal mask airway (LMA) does not reliably protect the lungs from regurgitated stomach contents and should be avoided in patients at an increased risk for aspiration.[34,35] In a meta-analysis of 12,901 low-risk cases, where the standard contraindications to the use of the LMA were followed (e.g., absence of gastrointestinal pathology, obesity, history of reflux, or emergency surgery), only three cases of aspiration were identified, representing an incidence of 2.3 per 10,000.[36]

Inadequate reversal of neuromuscular blockage at the end of surgery is an important risk factor for aspiration. After the administration of nondepolarizing neuromuscular blocking agents, it is essential to ensure adequate return of normal neuromuscular function. Residual paralysis decreases upper esophageal tone, coordination of the esophageal musculature during swallowing, and the hypoxic ventilatory drive.[37] These factors significantly increase the risk for aspiration. Adequate recovery of postoperative neuromuscular function cannot be guaranteed without objective neuromuscular monitoring. Good evidence-based practice dictates that clinicians should always quantitate the extent of neuromuscular blockade by objective monitoring (train-of-four monitoring).[37] To exclude clinically significant residual neuromuscular blockade, the train-of-four ratio, when measured mechanically or by electromyography, must exceed 0.9. If sufficient recovery (i.e., train-of-four ≥0.9) has not been documented objectively at the end of the surgical procedure, the neuromuscular block should be antagonized.

Prevention of Aspiration

In recent years, more liberal preoperative fasting guidelines have been promoted. In healthy adults without an increased risk of regurgitation or aspiration, solids should be avoided after midnight; however, a light meal such as dry toast may be considered up to 6 h before anesthesia, and clear liquids, such as water, coffee without milk, or fruit juice, can be given up to 2 h before induction.[38,39] Meta-analyses of randomized controlled trials comparing fasting times of 2–4 h versus more than 4 h report smaller gastric volumes and higher gastric pH values in adult patients given clear liquids 2–4 h before a procedure; this approach is currently endorsed by the ASA.[40]

Preoperative antacids, H2 receptor blockers, proton pump inhibitors, and prokinetic agents have been used to reduce the volume or acidity of the gastric contents. There is, however, a lack of data indicating that any of these drugs reduce the risk of aspiration pneumonitis.[41] The routine use of these drugs is not recommended by the ASA guidelines.[40] However, it is not unreasonable to use these drugs in patients at an increased risk of aspiration. It is important to realize that it takes time for the clinical effects of the acid suppressive drugs to manifest, and these drugs should, therefore, be dosed at least 2 h prior to induction.[42]

Standard teaching suggests that rapid sequence induction with cricoid pressure should be performed when intubating patients at an increased risk of aspiration. Cricoid pressure, known as the Sellick maneuver, is designed to occlude the cervical esophagus by compressing it between the cricoid cartilage and the vertebral bodies.[43] Passively regurgitated gastric contents are thereby prevented from entering the pharynx. Neither rapid sequence induction nor cricoid pressure has been prospectively studied and proven to decrease the incidence of aspiration.

Rapid sequence induction shortens the time between the onset of unconsciousness and securing the airway, which may be of benefit if the aspiration risk is high. However, the use of cricoid pressure is controversial.[44] The esophagus cannot be reliably occluded between the cricoid cartilage and the vertebral bodies. Studies in volunteers (men and nonpregnant women) clearly show that the esophagus often does not lie in the midline or that cricoid pressure displaces the esophagus laterally without occluding it.[45] More recent data suggest that the hypopharynx posterior to the cricoid cartilage is in continuity with the esophageal inlet and this hypopharyngeal area is occluded with the Sellick maneuver.[46] Cricoid pressure is often applied incorrectly or without the appropriate amount of force and may reduce visualization of the vocal cords and impede intubation. Although not proven to reduce the risk of aspiration during emergent intubations, cricoid pressure is currently considered the standard of care in this situation.

Clinical Presentation

Aspiration of gastric contents can present dramatically with a full-blown picture that includes gastric contents in the oropharynx, wheezing, coughing, shortness of breath, cyanosis, pulmonary edema, hypotension, and hypoxemia; this may progress rapidly to severe ARDS and death (Fig. 69-1). However, many patients may not develop signs or symptoms associated with aspiration, while others may develop a cough or wheeze. In some patients' aspiration may be clinically silent, manifesting only as arterial desaturation

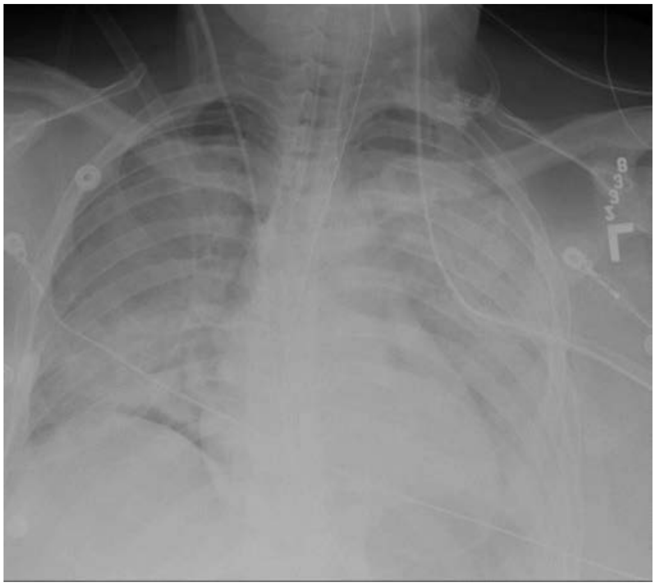

Figure 69-1 Chest radiograph demonstrating severe bilateral airspace disease (ARDS) in a patient who aspirated following anesthesia.

with radiologic evidence of aspiration. Warner et al. studied 67 patients who aspirated while undergoing anesthesia.[11] Of these patients, 42 (64%) were totally asymptomatic, 13 required mechanical ventilatory support for more than 6 hours, and 4 died.

Management of Aspiration Pneumonitis

The upper airway should be suctioned following a witnessed aspiration. Endotracheal intubation should be considered in patients who are unable to protect their airway. While common practice, the prophylactic use of antibiotics in patients with suspected or witnessed aspiration is not recommended. Similarly, the use of antibiotics shortly after an aspiration episode in a patient who develops a fever, leukocytosis, and a pulmonary infiltrate is discouraged as it may select for more resistant organisms in a patient with an uncomplicated chemical pneumonitis. However, empiric antimicrobial therapy is appropriate in patients who aspirate gastric contents in the setting of small bowel obstruction or in other circumstances associated with colonization of gastric contents (such as acid-suppressive therapy and tube feeds).

Antimicrobial therapy should be considered in patients with an aspiration pneumonitis that fails to resolve within 48 h. Empiric therapy with broad-spectrum agents is recommended. Antimicrobials with anaerobic activity are not routinely required.

Recently, serum procalcitonin has emerged as a potential biomarker that has been postulated as useful in discriminating bacterial infections from nonbacterial inflammatory disorders.[47] El-Solh et al. investigated the predictive accuracy of serum procalcitonin in distinguishing aspiration with bacterial pneumonia from "sterile" aspiration pneumonitis.[6] In this study, serum procalcitonin levels had poor diagnostic value in separating bacterial pneumonia from aspiration pneumonitis based on quantitative bronchoalveolar lavage culture. This finding is not surprising, considering that proinflammatory mediators play a central role in the pathophysiology of both syndromes and are responsible for the transcription of procalcitonin.[48]

Immunomodulating Agents and Pneumonitis

Corticosteroids are potent anti-inflammatory agents that act largely by repression of the transcriptional activity of NF-κB. Glucocorticoids have been used in the management of aspiration pneumonitis since 1955.[49–51] However, their role as monotherapy appears limited, possibly due to their limited effect on neutrophils and ROS.

Vitamin C, acting synergistically with low-dose corticosteroids, has emerged as an important strategy in treating various conditions characterized by widespread and profound inflammation.[52] Vitamin C is a potent antioxidant and inhibitor of NADPH oxidase and would likely reduce the severity of acute lung injury after acid aspiration.[53] In addition, vitamin C inhibits NETosis.[54] We have previously described two patients with "anesthesia"-related aspiration pneumonitis and severe ARDS who were treated with hydrocortisone, ascorbic acid, and thiamine (HAT therapy) and who appeared to respond dramatically to this intervention.[55] A recent prospective, randomized, controlled trial demonstrated that high-dose intravenous vitamin C reduced mortality in patients with ARDS.[56] Additional studies are required to confirm these findings to be considered for patients with acid aspiration–induced acute lung injury.

ASPIRATION PNEUMONIA

Aspiration pneumonia refers to the development of a radiographic infiltrate and clinical features of consistent with pneumonia in a patient with risk factors for increased oropharyngeal aspiration (Fig. 69-2). Approximately half of all healthy adults aspirate small amounts of oropharyngeal secretions during sleep. Presumably, the low virulent bacterial burden of normal pharyngeal secretions, together with forceful coughing, active ciliary transport, and normal humoral and cellular immune mechanisms result in clearance of the inoculum, without sequelae. However, if the mechanical, humoral, or cellular mechanisms are impaired or if the aspirated inoculum is large enough, pneumonia may follow.

Any condition that increases the volume or bacterial burden of oropharyngeal secretions in the setting of impaired host defense mechanisms may lead to aspiration pneumonia. Indeed, in stroke patients undergoing swallow evaluation there is a strong correlation between the volume of the aspirate and the development of pneumonia.[57] Factors that increase oropharyngeal colonization with potentially pathogenic organisms and that increase the bacterial load may augment the risk of aspiration pneumonia. The clinical setting in which pneumonia develops largely distinguishes

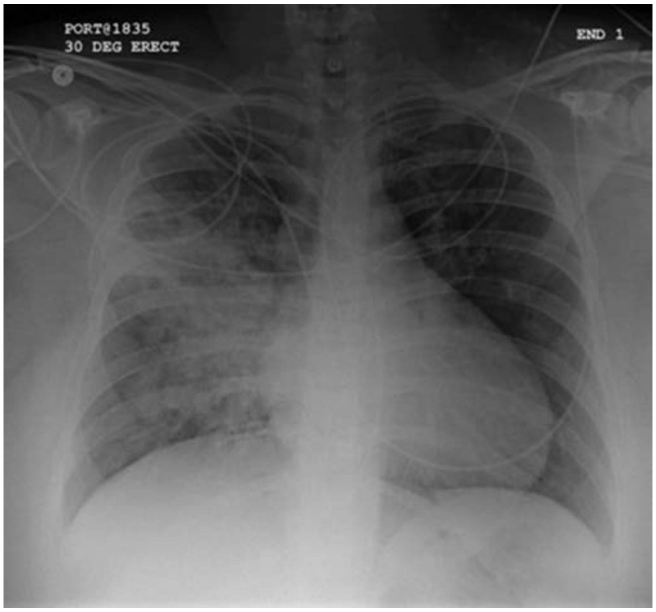

Figure 69-2 Opacification of the right perihilar region and superior segment of the right lower and upper lobes consistent with aspiration pneumonia in a 75-year-old patient who suffered a stroke.

aspiration pneumonia from other forms of pneumonia. However, there is much overlap. This is illustrated by the fact that otherwise healthy elderly patients with "community-acquired pneumonia" have been demonstrated to have a significantly higher incidence of silent aspiration when compared with age-matched controls.[58]

■ Epidemiology

The lack of specific and sensitive markers of aspiration makes the epidemiologic study of aspiration syndromes difficult. Furthermore, most studies do not make the distinction between aspiration pneumonitis and aspiration pneumonia. Nevertheless, several studies list "aspiration pneumonia" as the cause of community-acquired pneumonia (CAP) in 5% to 15% of cases.[59,60] CAP is a major cause of morbidity and mortality in the elderly, and it is likely that aspiration is the major cause of pneumonia in these patients. Epidemiologic studies have demonstrated that the incidence of pneumonia increases with aging, with the risk being almost six times higher in those over the age of 75 years, compared with those less than 60 years of age.[61,62] The attack rate for pneumonia is highest among those in nursing homes.[63]

■ Dysphagia in Aspiration Pneumonia

Swallowing is a complex function with both voluntary and reflexive components. Five cranial nerves and more than 50 muscles in the head and neck are involved in oropharyngeal swallowing. Both brainstem and cortical areas are involved in the neural processing of swallowing. The coordination of swallowing requires bilateral input from the sensorimotor cortex with descending input to the brainstem medullary swallowing center.[64] Functional and anatomic imaging studies have identified several sites that play an important role in swallowing, including the primary sensorimotor cortex, insula, anterior cingulate, internal capsule, basal ganglia, and thalamus.

The swallowing process can be divided into the oropharyngeal phase and esophageal phase.[65] The oropharyngeal phase includes biting and chewing in the oral cavity, and the transport of food into the pharynx. In simplified terms, this process is accompanied by elevation and anterior movement of the larynx to meet with the epiglottis for protection of the airway. It is followed by passage of the bolus through the upper esophageal sphincter into the esophagus (esophageal phase). During the esophageal phase, the lower esophageal sphincter relaxes, and food is advanced into the stomach by peristalsis and gravity.

Dysphagia refers to difficulty in swallowing. The severity of dysphagia varies from moderate difficulty to complete inability to swallow. Dysphagia is the major risk factor leading to aspiration pneumonia. In addition, dysphagia contributes significantly to protein-energy malnutrition and dehydration. Impairment in any component of the swallow mechanism, including anatomic abnormities of the upper airway or esophagus, can lead to dysphagia. Dysphagia has traditionally been associated with brainstem and bilateral cerebral infarction, although it has more recently been shown to occur in isolated cerebral infarctions as well. Furthermore, dysphagia is commonly associated with silent cerebral infarction.

Dysphagia is remarkably common in Westernized nations and is a major cause of morbidity and mortality. Indeed, aspiration pneumonia is probably the final common pathway by which most chronically ill patients die. It has been estimated that more than 16 million senior citizens in the United States suffer from dysphagia.[66] Furthermore, an additional 300,000 to 600,000 patients develop dysphagia each year in the United States from neurologic disorders.[67] Dysphagia affects more than 30% of patients who have had a cerebrovascular accident; 52%–82% of patients with Parkinson's disease; 84% of patients with Alzheimer's disease; up to 40% adults aged 65 years and older; and more than 60% of elderly institutionalized patients.[68]

TABLE 69-3 Risk Factors for Dysphagia and Aspiration Pneumonia

- Cerebrovascular disease
  - Ischemic stroke
  - Hemorrhagic stroke
  - Subarachnoid hemorrhage
- Degenerative neurologic disease
  - Alzheimer dementia
  - Multi-infarct dementia
  - Parkinson disease
  - Amyotrophic lateral sclerosis (motor neuron disease)
  - Multiple sclerosis
- Head and neck cancer
  - Oropharyngeal malignancy
  - Oral cavity malignancy
  - Esophageal malignancy
- Other
- Scleroderma
- Diabetic gastroparesis
- Reflux esophagitis
- Presbyesophagus
- Achalasia

The efficiency of the swallow mechanism decreases with aging, increasing the risk of aspiration and pneumonia in the elderly. Kikuchi et al. evaluated the occurrence of silent aspiration in otherwise "healthy elderly patients" with CAP and age-matched control subjects using indium^{111} chloride scanning.[58] Silent aspiration was demonstrated in 71% of patients with CAP compared to 10% in control subjects. The impaired swallow mechanism in the elderly may be attributed to diminished sensation, silent cerebral infarction, cerebral atrophy, a delay in the synapse conduction in the afferent inputs to the central nervous system, and lingual weakness (due to sarcopenia) caused by aging.[69,70]

■ Risk Factors for Dysphagia

The major risk factors for dysphagia are listed in Table 69-3. In patients with an acute stroke the incidence of dysphagia ranges from 40% to 70%.[71] Dysphagic patients who aspirate are at an increased risk of developing pneumonia.[72,73] Although dysphagia improves in most patients following a stroke, in many the swallowing difficulties follow a fluctuating course, with 10% to 30% continuing to have dysphagia with aspiration.[74,75]

■ Cough Reflex in Patients with Aspiration Pneumonia

An intact cough reflex is an important respiratory defense mechanism. Sekizawa et al. demonstrated a marked depression of the cough reflex in elderly patients with pneumonia.[76] Furthermore, the greater the derangement of the cough reflex the greater the risk of pneumonia.[77] Nakazawa et al. demonstrated impairment of the swallow and the cough reflex in elderly patients with aspiration pneumonia, but not in patients with dementia who had no prior history of aspiration pneumonia.[78]

Angiotensin-converting enzyme (ACE) modulates the cough reflex. Along with its effects that cleave angiotensin I to angiotensin II, ACE also metabolizes the protussive peptides substance *P* and bradykinin. Substance *P*, which is released from vagal sensory nerves in the pharynx and upper airways, mediates the cough reflex.

In one study, investigators found that substance *P* levels in sputum were reduced substantially in elderly patients with pneumonia.[79] Bradykinin, an inflammatory peptide that mediates cough due to ACE inhibitions, sensitizes airway sensory nerves and enhances the cough reflex. A number of reports indicate that the insertion/deletion (*I/D*) polymorphism of the ACE gene (ACE DD allele) is associated with an increased risk of pneumonia.[80,81] Furthermore, the use of ACE inhibitors is associated with a reduced risk of aspiration pneumonia (see "Pharmacologic Management," below).

Factors That Increase the Risk of Pneumonia in Patients Who Aspirate

While the presence of dysphagia and the volume of the aspirate are key factors that predispose patients to aspiration pneumonia, a number of other factors play an important role.[57] Colonization of the oropharynx is an important step in the pathogenesis of aspiration pneumonia. The elderly have increased oropharyngeal colonization with pathogens such as *Staphylococcus aureus* and aerobic gram-negative bacilli (e.g., *Klebsiella pneumoniae*, *Escherichia coli*). Although this increased colonization may be transient, it underlies the increased risk in the elderly of pneumonia with these pathogens. Furthermore, colonization of dental plaque may be an important risk factor for aspiration pneumonia.[82]

The defects in host defenses that predispose to enhanced colonization with these organisms are uncertain; however, dysphagia with a decrease in salivary clearance and poor oral hygiene may be major risk factors.[83] Residents of long-term care facilities are prone to poor oral health due to lack of oral hygiene care as well as conditions of periodontal or dental disease. Langmore et al. reported that in elderly patients the number of decayed teeth and never or only occasionally brushing teeth were independent predictors of aspiration pneumonia.[84] Similarly, Azapazhooh and Leake performed a systematic review demonstrating that the presence of cariogenic and periodontal pathogens in dental plaque and saliva and decayed teeth were independent predictors of aspiration pneumonia.[85] Others have demonstrated that persons with 10 or more periodontal pockets had an increased risk of death from pneumonia.[86]

Proton pump inhibitors increase gastric and oropharyngeal colonization with potentially pathogenic organisms. Investigators have reported that the concurrent use of proton pump inhibitors in patients over the age of 60 increased the risk for community-acquired (aspiration) pneumonia.[87]

Diagnosis and Management of Aspiration Pneumonia

There is no "gold standard" diagnostic test for aspiration pneumonia. Furthermore, in patients with aspiration pneumonia, unlike the case of aspiration pneumonitis, the episode of aspiration is generally not witnessed. Rather, the diagnosis is inferred when a patient with known risk factors for aspiration develops clinical features compatible with pneumonia (e.g., fever, shortness of breath, purulent sputum) with an infiltrate in a characteristic bronchopulmonary segment (Fig. 69-2). In patients who aspirate in the recumbent position, the commonest sites of involvement are the posterior segments of the upper lobes and the apical segments of the lower lobes. In patients who aspirate in the upright or semirecumbent position, the basal segments of the lower lobes are favored. The usual picture is an acute pneumonic process that runs a course similar to that of a typical CAP. However, when untreated, these patients appear to have a higher incidence of cavitation and lung abscess formation.[88]

Antimicrobial therapy is essential in patients with aspiration pneumonia. The choice of antibiotics depends on the setting in which the aspiration occurs, as well as the patient's premorbid condition. Factors to be considered include whether the aspiration occurred in the community or in a health care facility, and patient characteristics such as alcoholism, oral hygiene, injection drug use, and the recent use of antibiotics or acid-suppressive therapy.[89]

In otherwise "healthy" outpatients, a narrow-spectrum antibiotic that targets organisms that include *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Hemophilus influenzae* is recommended. However, most patients with aspiration pneumonia have risk factors for colonization and infection with aerobic Gram-negative organisms and require treatment with antimicrobials such as third-generation cephalosporins, fluoroquinolones, piperacillin, or carbapenems.[89–92] In addition, vancomycin or linezolid should be considered in patients at risk of infection with methicillin-resistant *Staphylococcus aureus* (MRSA).

Although commonly prescribed (and often considered the standard of care), antimicrobials with specific anaerobic activity are not routinely warranted. The anaerobic bacteria that colonize the oropharynx are intrinsically of low virulence. In an experiment dating back to 1930, Smith introduced bacteria isolated from patients with Vincent's angina into the lungs of rabbits.[93] Cultures of a single organism failed to produce pneumonia; only when multiple different organisms were instilled into the lungs did the animals develop pneumonia (synergistic anaerobic infection). In the most rigorous study to date, El-Sohl et al. performed protected quantitative bronchial sampling in 95 patients with severe aspiration pneumonia.[92] Of the 67 pathogens identified, Gram-negative enteric bacteria were the predominant organisms isolated (49%), followed by anaerobic bacteria (16%) and *Staphylococcus aureus* (12%). A single anaerobic bacterium was isolated from 11 patients, usually in association with a Gram-negative pathogen. Although 7 cases with anaerobic isolates received initially inadequate antimicrobial therapy, 6 had effective clinician response. Antimicrobials with specific anaerobic activity may only be indicated in patients with periodontal disease, patients expectorating putrid sputum, and those with a necrotizing pneumonia or lung abscess on chest radiograph.[2,89–91]

Assessment and Management of Dysphagia

All elderly patients with CAP, as well as patients with a recent cerebrovascular accident and those with degenerative neurologic diseases, should be referred to a speech and language pathologist (SLP) for a formal swallow evaluation[73,94] (Video 69-1). Those patients with dysphagia require the formulation and implementation of an individualized management strategy. A clinician's bedside assessment of the cough and gag reflex is unreliable in screening for patients at risk of aspiration. Because objective swallowing evaluation can be performed with a nasogastric tube or feeding tube in place, it is not necessary to remove the tube (and interrupt enteral feedings) to evaluate dysphagia. Similarly, there is no contraindication to leaving a nasogastric tube in place to supplement oral alimentation.[95]

Video 69-1 An 82 year-old male admitted with PNA, required multiple intubations and eventual tracheostomy. Fiberoptic endoscopic evaluation of swallowing (FEES) completed with #5XLT proximal/cuffless tracheostomy (patient capped on room air) and Dobhoff feeding tube in place. FEES revealed a severe pharyngeal dysphagia. There is pooling of secretions throughout pharynx/larynx (valleculae and pyriform sinuses) with aspiration of secretions. With pureed texture there is residue throughout the pharynx suggestive of generalized reduced pharyngeal contraction. The residue in the valleculae is a result of reduced base of tongue retraction, epiglottis dysfunction, and poor hyoid elevation. The residue in the pyriform sinuses is a result of cricopharyngeus dysfunction/inadequate upper esophageal sphincter opening. There is a delayed pharyngeal swallow response with nectar consistency with bolus spilling to the pyriform sinuses resulting in + aspiration before/during/after the swallow response due to reduced arytenoid tilt and vocal fold adduction. *(Used with permission of Randy Dubin.) Video available on AccessMedicine.com.*

The management of patients with dysphagia requires the coordinated expertise of a number of health care professionals, including the patient's primary care physician, pulmonologist, SLP, clinical dietician, occupational therapist, physiotherapist, nurse, oral hygienist, dentist, and primary caregivers. The goal is to optimize the safety, efficiency, and effectiveness of the oropharyngeal swallow, to maintain adequate nutrition and hydration, and to improve oral hygiene. Enhanced quality of life, wherever possible, should direct management, and oral intake (when possible) is preferred over tube feeding.

A fundamental principle of rehabilitation is that the best therapy for any activity is the activity itself; as swallowing may be considered the best therapy for swallowing disorders, rehabilitation should be aimed at identifying ways of ensuring safe and effective swallowing in individual patients. Current treatment for dysphagia includes prevention of aspiration in the form of diet and fluid modifications, compensatory maneuvers, position changes, and rehabilitation exercises.[96]

Diet modification is a common treatment for dysphagia. Modifications in food consistency are individually determined by means of the clinical swallow or videofluoroscopic swallow evaluation. Reduction in bolus volume and enhancement of bolus viscosity significantly improve the safety of swallowing and reduce the risk of aspiration.[69] The SI physical unit of dynamic viscosity is the pascal-second (Pa·s). The prevalence of aspiration is maximal with water and thin fluids (20 Pa·s) and decreases with nectar (270 Pa·s) and pudding (3900 Pa·s) boluses.[69] By increasing the viscosity or thickness of the food or liquid bolus in patients with oral sensory or motor deficits, the material is less likely to escape from the oral cavity, fall into the laryngeal inlet, or penetrate the incompletely sealed larynx during the delay before pharyngeal swallowing starts. Videofluoroscopic studies have demonstrated that increasing viscosity of liquids to that of pudding significantly reduces the risk of aspiration.[97,98]

In addition to changes in diet, maintenance of oral feeding often requires compensatory techniques to reduce aspiration or to improve pharyngeal clearance. A variety of behavioral techniques are used, including modifications in posture, head position and respiration, and specific swallowing maneuvers. The chin-down posture has been suggested to reduce the risk of aspiration.[98–100] Welch et al. noted that the posterior shift of anterior pharyngeal structures with the chin-down posture improved airway protection.[101] The preferred intervention in patients with dysphagia and the impact of these interventions on the risk of aspiration pneumonia is, however, unclear.[102]

Neuromuscular electrical stimulation (NMES) is a relatively new treatment for oropharyngeal dysphagia.[103–107] NMES for dysphagia entails applying electrodes to the muscles of the head and neck, and stimulating those muscles that are weakened or hemiparetic by means of electric pulses. This is generally combined with the subject swallowing food or fluids that are predetermined to represent the most appropriate consistency that the person can tolerate without aspiration. Clinical studies to date suggest that the early application of NMES appears to be a useful supplementary treatment of traditional dysphagia treatment to help rehabilitate acute/subacute dysphagic stroke patients by improving their swallowing coordination.[103–107]

Tube Feeding

Tube feeding is not essential in all patients who aspirate. Short-term tube feeding, however, may be indicated in elderly patients with severe dysphagia and aspiration in whom improvement of swallowing is likely to occur.

Nakajoh et al. demonstrated that the incidence of pneumonia was significantly higher in stroke patients with dysphagia who were fed orally compared with those who received tube feeding (54.3 vs. 13.2%; $p < 0.001$), despite the fact that the orally fed patients had a higher functional status (higher Barthel index).[77]

The FOOD trials consisted of two large randomized studies that enrolled dysphagic stroke patients.[108] In the first trial, patients enrolled within 7 days of admission were randomly allocated to early tube feeding or no tube feeding. Early tube feeding was associated with an absolute reduction in risk of death of 5.8%. The second trial allocated patients to early nasogastric feeding or early feeding via a percutaneous endoscopic gastrostomy (PEG) tube. PEG feeding was associated with an absolute increase in the risk of death of 1% and an increased risk of death or poor outcome of 7.8%. Patients with a PEG were less likely to be transitioned to oral feeding than the nasogastric group and were more likely to be living in an institution. This may in part explain the higher mortality of the PEG-fed patients. Furthermore, it is interesting to note that PEG-fed patients were more likely to develop pressure sores, suggesting that these patients may have been cared for differently from a nursing perspective. The results of the FOOD trials suggest that dysphagic stroke patients should be fed early via a nasogastric or feeding tube and transitioned to oral feeding as their dysphagia resolves. Those patients whose dysphagia does not resolve may be candidates for placement of a PEG tube.

Oral Hygiene

Dental plaque, as well as "tongue coating," serve as a reservoir of potentially pathogenic organisms.[82] Occupants of residential homes have been shown to have poor oral hygiene and rarely receive treatment from dentists and oral hygienists.[109] An aggressive protocol of oral care will reduce colonization with potentially pathogenic organisms and decrease the bacterial load, measures that have been demonstrated to reduce the risk of aspiration pneumonia.[110–113] Oral care should not be overlooked in edentulous patients, as "tongue cleaning" is associated with a decreased oropharyngeal bacterial load.[114,115]

Pharmacologic Management

The neurotransmitter substance P is believed to play a major role in both the cough and swallow sensory pathways. ACE inhibitors prevent the breakdown of substance P and may theoretically be useful in the management of patients with aspiration pneumonia. A number of studies have demonstrated a lower risk of aspiration pneumonia in stroke patients treated with an ACE inhibitor compared with other antihypertensive agents.[116,117] This observation was initially noted in Japanese patients; it has been suggested that this benefit was restricted to Asian populations.[118] Furthermore, it has been postulated that lipophilic ACE inhibitors may be more beneficial than hydrophilic ACE inhibitors.[119] However, a population-based case-control study from the United Kingdom demonstrated that the current prescription for an ACE inhibitor was associated with a reduction of the risk of pneumonia in the general population (OR, 0.75; 95% CI, 0.65–0.86).[120] Nicergoline, an ergot alkaloid derivative, has been demonstrated to upregulate substance P and improve dysphagia with an efficacy similar to that of ACE inhibitors.[121] Additional studies are required with this drug to determine its role in preventing aspiration pneumonia.

Sedative medication has been demonstrated to increase the risk of pneumonia in residents of long-term care facilities and should therefore be avoided.[122] The prescription of phenothiazines and haloperidol should be very carefully considered, as they reduce oropharyngeal swallow coordination, causing dysphagia.[123,124] Medications that dry up secretions, including antihistamines and drugs with anticholinergic activity, make it more difficult for patients to swallow and should therefore also be avoided.[123,125]

DIFFUSE ASPIRATION BRONCHIOLITIS

Occult aspiration can result in lung damage with a variety of radiographic, clinical, and histologic manifestations. Occult aspiration

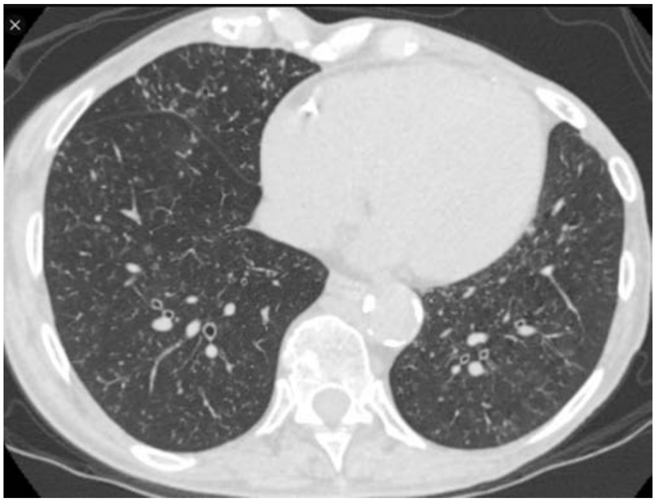

Figure 69-3 Computed tomographic scan of a patient with diffuse aspiration bronchiolitis with diffuse centrilobular nodules with a tree-in-bud pattern.

in the elderly is usually associated with esophageal dysmotility, gastroesophageal reflux disease (GERD), and neurologic impairment (dysphagia) and frequently presents with acute onset of symptoms while sleeping.[126] Diffuse aspiration bronchiolitis is a distinct clinical entity that was first defined by Matsuse et al. in 1996 as a syndrome characterized by chronic bronchiolar inflammation from recurrent aspiration of foreign matter (food).[7] Their case series was based on autopsy findings and represented an elderly, chronically debilitated population. Dysphagia was recorded in more than half of the patients, and two-thirds of patients were bedridden.

Diffuse aspiration bronchiolitis (DAB) should be suspected in elderly patients with recurrent episodes of bronchorrhea, bronchospasm, and dyspnea. However, this syndrome has been reported in middle-aged patients (mean age, 50 years) with "asymptomatic" GERD.[127] Typical findings on the chest radiograph include the presence of regional or disseminated small nodular shadows and hyperlucency. Air space consolidation is relatively rare. Chest CT scans demonstrate diffuse centrilobular nodules with a tree-in-bud pattern (Fig. 69-3).[128] It is likely that this disease is underrecognized and therefore often inappropriately managed. Macrolides appear to reduce the number of acute exacerbations of DAB.[129]

CONCLUSIONS

Aspiration pneumonitis and pneumonia are common clinical syndromes. Aspiration pneumonitis follows the aspiration of gastric contents, usually in patients with a marked decreased level of consciousness. Treatment of aspiration pneumonitis is essentially supportive; however, corticosteroids and other immunomodulating agents may have a role in these patients. Aspiration pneumonia occurs in patients with dysphagia and usually presents as a "community-acquired pneumonia," with a focal infiltrate in a dependent bronchopulmonary segment. Patients with aspiration pneumonia require treatment with broad-spectrum antibiotics and management of the underlying dysphagia. Diffuse aspiration bronchiolitis presents with radiographic evidence of widespread centrilobular and tree-in-bud opacities; clinicians must be aware of the possibility of occult aspiration in order to make the correct diagnosis.

CHAPTER 70

Pulmonary Alveolar Proteinosis Syndrome

Bruce C. Trapnell
Cormac McCarthy
Brenna Carey

INTRODUCTION

Pulmonary alveolar proteinosis (PAP) is a rare syndrome characterized by myeloid cell dysfunction, progressive pulmonary surfactant accumulation, hypoxemia, innate immunodeficiency, and in some individuals, serious infections, pulmonary fibrosis, respiratory failure, and death.[1] While PAP-causing diseases are clinically and mechanically heterogeneous, they are usefully categorized based on pathogenesis into primary, secondary, and congenital PAP. Primary PAP is caused by impaired granulocyte-macrophage colony-stimulating factor (GM-CSF)-dependent surfactant clearance by alveolar macrophages and accounts for about 90% of cases.[2] Secondary PAP occurs as a consequence of a comorbid condition that impairs surfactant clearance by alveolar macrophages and accounts for about 5% to 10% of cases.[3] Congenital PAP—more appropriately, surfactant metabolic dysfunction disorders—constitutes a clinically distinct and heterogeneous group of genetic diseases associated with acute respiratory failure at birth from surfactant deficiency/dysfunction or progressive pulmonary fibrosis, production of abnormal surfactant, and varying degrees of surfactant accumulation (hence, their consideration as PAP); these disorders account for less than 5% of cases.[4] Importantly, research on the pathogenesis of primary PAP identified a critical role for GM-CSF in surfactant homeostasis, alveolar stability, lung function, and host defense. Because of its increased occurrence and greater research attention, primary PAP is the primary focus of this chapter; data for secondary and congenital PAP are provided when available.

PATHOGENESIS

In their 1958 report, Rosen et al.[5] established that the material accumulating in alveoli in PAP was composed primarily of lipids with lesser amounts of proteins, and minimal carbohydrate. Subsequent research identified the material to be primarily surfactant (with an increased cholesterol-to-phospholipid ratio) with smaller amounts of uncleared cell debris and cytokines.[6,7] In about 90% of patients, pathogenesis is driven by disruption of GM-CSF signaling to alveolar macrophages,[1,8–10] which blocks their terminal differentiation in the lungs, their ability to clear surfactant, and a number of other functions.[11–14]

GM-CSF is a 23-kDa cytokine produced by respiratory epithelium and other cells,[15–17] initially identified by its ability to stimulate the formation of macrophage and granulocyte colonies from hematologic progenitors and subsequently shown to stimulate functions in mature myeloid and other cells. While GM-CSF is similarly expressed in humans and mice and has remarkably similar regulatory effects on their respective target cell populations, the murine and human homologues are neither immunologically cross-reactive nor functionally interchangeable. GM-CSF binds to cell surface receptors composed of a GM-CSF–binding α-chain (CD116), an affinity-enhancing β-chain (CD131), and an associated Janus kinase 2 (JAK2). Ligand binding activates multiple intracellular signaling pathways including signal transducer and activator of transcription 5 (STAT5), regulating diverse functions of myeloid cells including survival, differentiation, proliferation, and host defense priming.[17,18] GM-CSF also has regulatory effects on lymphocytes and alveolar epithelial cells.[19–21]

In primary PAP, pathogenesis is caused by disruption of GM-CSF signaling by neutralizing GM-CSF autoantibodies (autoimmune PAP) or by recessive mutations in *CSF2RA* or *CSF2RB* (encoding GM-CSF receptor α-chain [CD116] or β-chain [CD131], respectively) (hereditary PAP).[1,2,22–28]

■ Surfactant Homeostasis

Surfactant is an oily substance vital to lung function normally present at the air–liquid–tissue interface as a thin layer or multilayer several molecules thick. It is composed of (roughly) ~80% phospholipids, ~10% neutral lipids (primarily cholesterol), ~10% proteins (surfactant protein [SP]-A, -B, -C and -D), and less than 1% carbohydrate.[29] SP-B and SP-C are hydrophobic phosphoproteins that contribute significantly to the surface active properties of surfactant.[30] SP-A and SP-D are hydrophilic collectin family members that contribute to lung host defense.[31] Surfactant lipids and proteins are synthesized, stored, and secreted into the alveoli by type II alveolar epithelial cells. In the extracellular space, surfactant "large aggregates" contribute to formation of a thin film that reduces surface tension on the alveolar wall thereby stabilizing the alveolus.[32] Surfactant is expelled from the film as "small aggregates" that are internalized by type II cells and alveolar macrophages in roughly equal amounts (Fig. 70-1). Type II cells recycle and catabolize internalized surfactant in roughly equal proportions via mechanisms that are incompletely defined but that do not appear to require regulation by GM-CSF.[32–34] In contrast, alveolar macrophages catabolize internalized surfactant phospholipids and proteins, and export cholesterol under regulation by GM-CSF, which is required for cholesterol homeostasis to stimulate the rate of excretion.[13,35]

■ Animal Models of PAP

The discovery that gene-ablated, GM-CSF-deficient (*Csf2*^{KO}) mice develop a pulmonary disease indistinguishable from primary PAP provided an important pathogenic clue (Fig. 70-2).[22,23] In *Csf2*^{KO} mice, neither production of surfactant by type II cells nor its uptake by alveolar macrophages was impaired.[36,37] Rather, surfactant clearance by alveolar macrophages was impaired.[25] Replacement of GM-CSF in the lungs by direct instillation or expression in airway epithelium corrected the lung disease.[20,38,39] Disruption of the GM-CSF receptor β (i.e., *Csf2rb*^{KO} mice) caused a similar lung phenotype[40] that could be corrected by bone marrow transplantation, which indicated the critical cell type driving pathogenesis was myeloid (i.e., alveolar macrophages) and not epithelial (i.e., type II cells) in origin.[41] PAP also occurs in mice deficient in the GM-CSF receptor α chain—*Csf2ra*^{KO} mice.[42] PAP in *Csf2ra*^{KO} and *Csf2rb*^{KO} mice can be corrected by direct instillation of wild-type congenic macrophages into the lungs without myeloablation, thus verifying the alveolar macrophage as the primary cellular site of pathogenesis in PAP caused by the disruption of GM-CSF signaling.[42,43] Surfactant clearance in *Csf2*^{KO} alveolar macrophages could be also corrected by retroviral expression of PU.1, a transcription factor normally expressed in murine alveolar macrophages in vivo under tight regulatory control of pulmonary GM-CSF.[44] PU.1 also mediates the effects of GM-CSF on surfactant clearance and other functions in human alveolar macrophages.[14] These studies established

Figure 70-1 Schematic illustration depicting mechanisms of surfactant production, recycling, and catabolism. Surfactant phospholipids and proteins are synthesized in type II alveolar epithelial cells that line pulmonary alveoli. Surfactant B and C precursor proteins are processed, transported to lamellar bodies, and then secreted into the alveolar space where they interact with surfactant protein A to form tubular myelin. Surfactant monolayers and multilayers are formed from tubular myelin and function to reduce surface tension at the air–liquid–tissue interface, thus stabilizing the alveoli. Surfactant remnants are taken up and either catabolized or reutilized by type II alveolar epithelial cells. Alveolar macrophages play a critical role in surfactant homeostasis by taking up and catabolizing surfactant remnants. GM-CSF is required to maintain surfactant homeostasis and acts by stimulating catabolism of surfactant lipids and proteins in alveolar macrophages. *(Reproduced with permission from Whitsett JA, Wert SE, Trapnell BC. Genetic disorders influencing lung formation and function at birth. Hum Mol Genet. 2004;13[Spec No 2]:R207–R215.)*

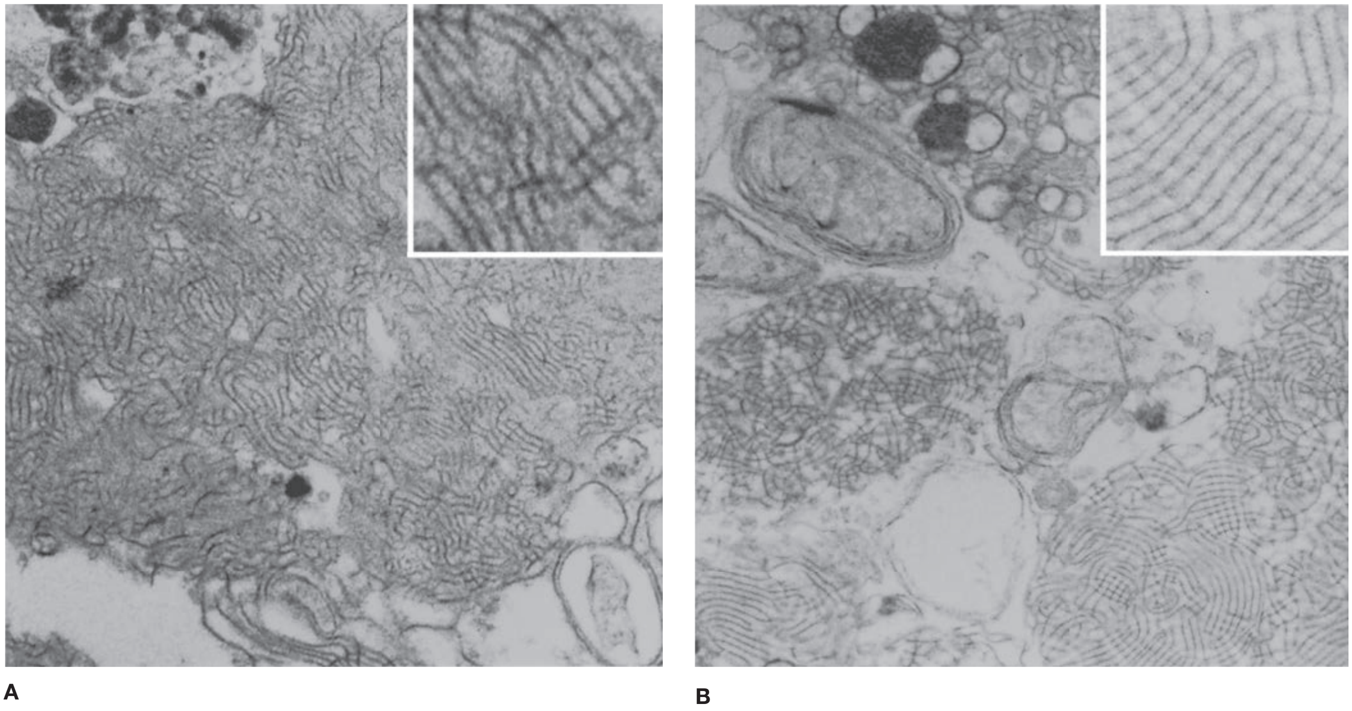

Figure 70-2 Ultrastructural appearance of the sediment from the lungs of a human patient with primary PAP (**A**) and a GM-CSF–deficient mouse (**B**). Note the presence of lamellated, fused membrane structures and amorphous debris (uranyl acetate, ×30,000).

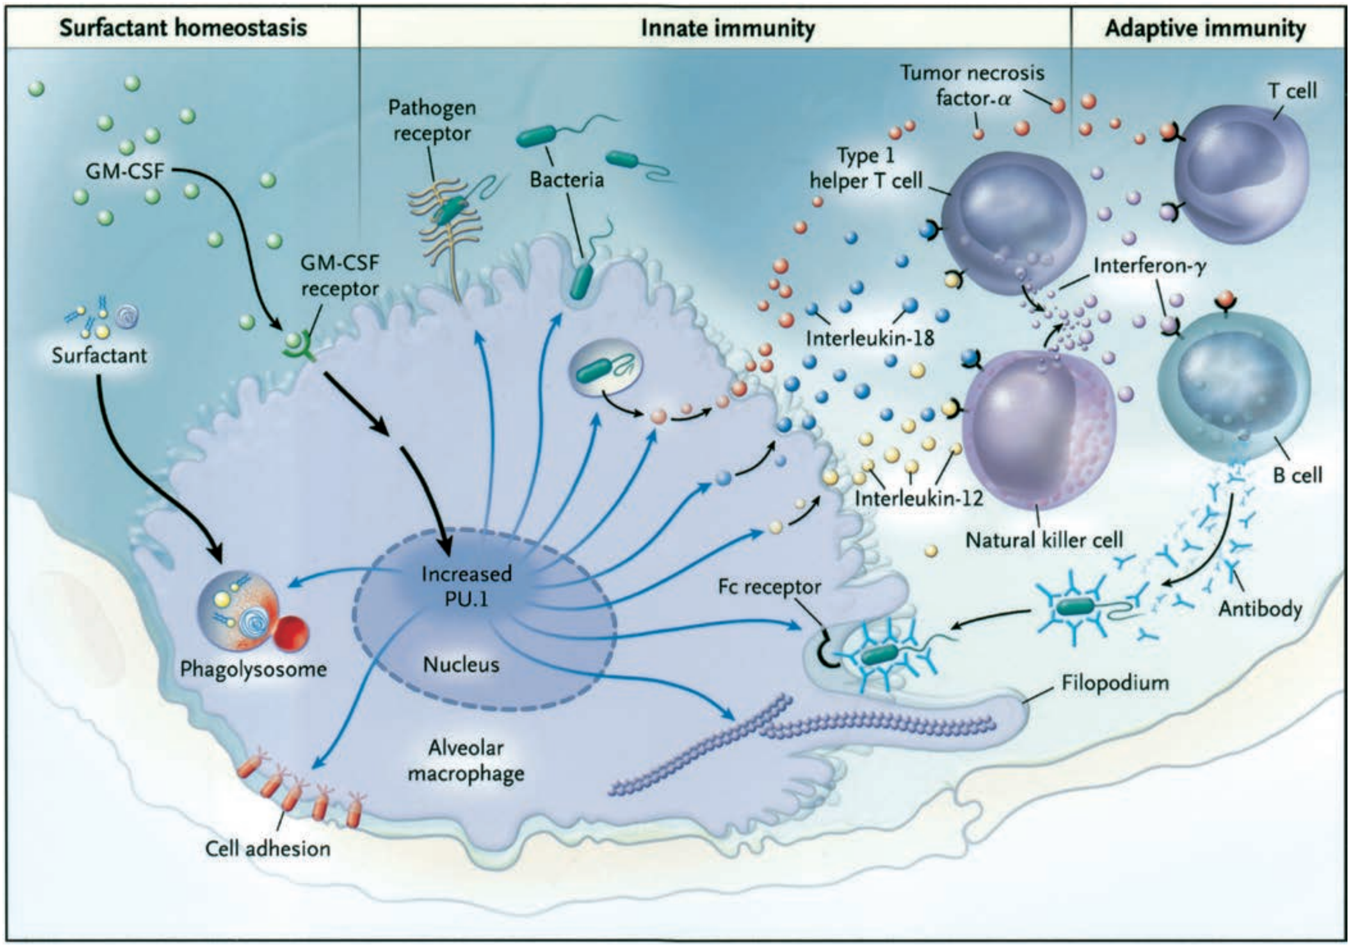

Figure 70-3 Role of GM-CSF in modulating the function of alveolar macrophages in mice. Pulmonary GM-CSF stimulates increased levels of the transcription factor PU.1 in alveolar macrophages in the lungs in vivo. Alveolar macrophages from mice deficient in GM-CSF have a number of functional defects including defects in cellular adhesion, catabolism of surfactant proteins and surfactant lipids, expression of pathogen-associated molecular pattern receptors (e.g., Toll-like receptors and the mannose receptor), Toll-like receptor signaling, phagocytosis of pathogens, intracellular killing of bacteria (independent of uptake), pathogen-stimulated secretion of cytokines (tumor necrosis factor α, interleukin [IL]-12, and IL-18), and Fc-receptor–mediated phagocytosis. Cytoskeletal organization is abnormal and may in part account for defects in phagocytosis. The ability of alveolar macrophages to release IL-12 and IL-18 severely impairs the interferon γ response to pulmonary infection, thus impairing an important molecular connection between innate and adaptive immunity in the lung. Retroviral-mediated expression of PU.1 in alveolar macrophages from GM-CSF knockout mice corrects all these defects, suggesting that GM-CSF stimulates terminal differentiation of the macrophages primarily through the master transcription factor PU.1. The *blue arrows* represent the functions regulated by PU.1 that are affected by the absence of GM-CSF. *(Reproduced with permission from Trapnell BC, Whitsett JA, Nakata K. Pulmonary alveolar proteinosis. N Engl J Med. 2003;349(26):2527–2539.)*

that GM-CSF, via PU.1, was required for surfactant clearance in alveolar macrophages in humans and mice (Fig. 70-3).

Passive immunization with human PAP patient–derived neutralizing GM-CSF autoantibodies resulted in recapitulation of the cardinal pathologic features of autoimmune PAP in nonhuman primates.[9,10] The abnormalities induced in alveolar macrophages included impaired GM-CSF signaling, GM-CSF–dependent gene expression (including PU.1), surfactant clearance, and increased cholesterol and cholesterol ester accumulation within intracytoplasmic droplets (as a cell-protective mechanism responding to increased cholesterol) resulting in foamy-appearing alveolar macrophages. Murine macrophages also require expression of the transcription factor PPARγ in order to clear surfactant normally.[45–47] Finally, a series of studies have identified GM-CSF/PU.1/PPARγ-regulated expression of the cholesterol transporter ABCG1 as critical for cholesterol export and surfactant clearance by human and mouse alveolar macrophages.[6,7,48] These animal models provide strong support for disruption of the GM-CSF signaling axis (GM-CSF>PU.1>PPARγ>ABCG1) as the critical driver of PAP pathogenesis.

As a model of secondary PAP, depletion of alveolar macrophages has been shown to increase lung surfactant pool size in rats.[49] Congenital PAP models have been created in mice by disruption of the genes required for normal surfactant production (*Sftpb*, *Sftpc*, *Abca3*).[50–52]

■ Primary PAP

Autoimmune and hereditary forms of primary PAP are considered below.

Autoimmune PAP

A second important clue about the pathogenesis of the disease previously reported as idiopathic PAP, acquired PAP, and a number of other terms was its association with neutralizing, anti–GM-CSF autoantibodies (Fig. 70-4).[22,53] Subsequently, GM-CSF autoantibodies were shown to be (1) polyclonal, (2) composed of immunoglobulin

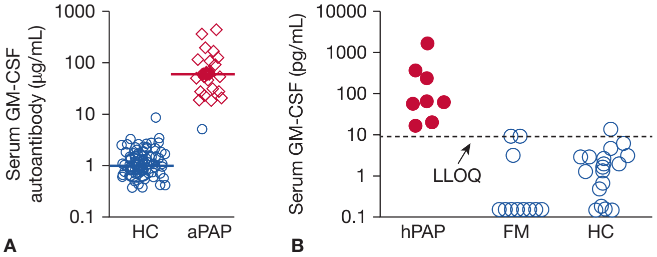

Figure 70-4 Biomarkers of use in identifying individuals with primary PAP. **A.** Serum GM-CSF autoantibody concentration. Shown are data for healthy controls (HCs) and patients with aPAP (autoimmune PAP). **B.** Serum GM-CSF concentration. Shown are data for children with hereditary PAP (hPAP) caused by recessive *CSF2RA* or *CSF2RB* mutations, members of their immediate family who were healthy (FM), or unrelated HCs. The lower limit of quantification (LLOQ) of the assay was 7.8 pg/mL *(dashed line)*. The serum levels of GM-CSF (median, interquartile range) in children with hPAP (52 pg/mL [28–101 pg/mL]) were increased compared with healthy family members (0.0 pg/mL [0.0–3 pg/mL]) and unrelated healthy controls (0.0 pg/mL [0.0–1.9 pg/mL]) ($n = 8, 11, 30$, respectively; $p < 0.001$; Kruskal–Wallis analysis of variance on ranks with comparisons using Dunn's method). *(**A.** Reproduced with permission from Uchida K, Nakata K, Suzuki T, et al: Granulocyte/macrophage-colony-stimulating factor autoantibodies and myeloid cell immune functions in healthy subjects. Blood. 2009;113(11):2547–2556; **B.** Reproduced with permission from Suzuki T, Sakagami T, Young LR, et al. Hereditary pulmonary alveolar proteinosis: pathogenesis, presentation, diagnosis, and therapy. Am J Crit Care Med. 2010;182(10):1292–1304.)*

G subclass 1 (IgG$_1$) and IgG$_2$ (in roughly equal proportions) with smaller amounts of IgG$_3$ and IgG$_4$, (3) of high affinity for binding GM-CSF—in the 3- to 20-pM range, exceeding that of the binding to the GM-CSF receptor alpha chain, and (4) capable of neutralizing GM-CSF bioactivity in vivo.[54,55] Notwithstanding, several findings were difficult to reconcile. GM-CSF autoantibodies were also present in healthy individuals albeit at lower levels,[55] and levels of GM-CSF autoantibody in PAP patients did not correlate with disease severity.[56] Reproduction of PAP in nonhuman primates by the injection of PAP patient–derived GM-CSF autoantibodies firmly established their critical role in the pathogenesis of idiopathic PAP.[9,10] The low levels of GM-CSF autoantibodies in healthy individuals[55] (and intravenous immune globulin[57,58]) and lack of correlation with disease severity in idiopathic PAP was explained by a model in which constitutive in vivo stimulation of GM-CSF–dependent myeloid cell functions (including surfactant clearance) declined in parallel with the level of GM-CSF autoantibody level until a concentration (known as the critical threshold) was reached where GM-CSF stimulated functions were reduced to zero (and could go no further).[55,59] This threshold level was similar in humans and passively immunized nonhuman primates.[9,10,55] These studies provided the evidence needed to demonstrate that GM-CSF autoantibodies were pathogenic and led to a recommendation to change the name from idiopathic PAP to autoimmune PAP.[59]

Hereditary PAP

While no humans with PAP caused by GM-CSF deficiency have been identified to date, in 2008, a child with GM-CSF autoantibody–negative PAP was found to have compound heterozygous mutations in *CSF2RA* (encoding GM-CSF receptor α) as the cause of familial PAP.[23] Additional patients were identified by exploiting use of a biomarker, increased serum GM-CSF, to screen sera from a repository including patients with PAP of unknown etiology, which identified a cohort of patients with PAP-causing *CSF2RA* mutations (Fig. 70-4).[24] Subsequently, *CSF2RB* mutations were identified as a cause of hereditary PAP.[25,60] Detailed characterization including molecular cloning and expression studies to recapitulate the receptor dysfunction established that the pathogenesis of hereditary PAP is caused by recessive or compound heterozygous mutations in the *CSF2RA* or *CSF2RB* genes. Subsequently, various mutations were identified in these genes as the cause of hereditary PAP including missense mutations, nonsense mutations, small insertions and deletions, exon deletion, and gene deletion.[23,24,26,28,60] Together, these studies defined the clinical presentation, pathogenesis, diagnosis, and therapy of hereditary PAP caused by disruption of GM-CSF signaling.

■ Secondary PAP

Results from a national registry confirmed that secondary PAP occurs in association with a heterogeneous group of underlying diseases including hematologic disorders, primarily myelodysplasia (76%–88% of cases); infectious diseases (2%–3%); other autoimmune diseases (7%); immunosuppression after organ transplantation (7%); and nonhematologic malignancies (5%).[61,62] Secondary PAP also occurs in association with (and presumably due to) heavy inhalation exposure to inorganic dusts (e.g., silica, titanium, aluminum) and other gasses and fumes, or as a consequence of systemic infections, for example, during human immunodeficiency virus (HIV) infection.[63,64] Secondary PAP appears to be caused by a reduction in the numbers or clearance capacity of alveolar macrophages, consistent with macrophage depletion studies in rats.[49]

■ Congenital PAP (Surfactant Metabolic Dysfunction Disorders)

PAP occurs in neonates, infants, and children in association with various defects in the genes encoding SP-B, SP-C, ABCA3—a lipid transporter expressed in type II alveolar epithelial cells—or TTF-1, a transcription factor essential for lung development and surfactant expression.[4,65–68] In contrast to primary and secondary PAP that are caused by reduced surfactant clearance, these disorders result from production of abnormal surfactant. While surfactant accumulation does occur to varying degrees in surfactant production disorders, these disorders are clinically, histopathologically, and pathogenically distinct from primary and secondary PAP.

■ The Emerging Role of GM-CSF in Innate Immunity

Csf2^{KO} mice have increased susceptibility to a broad range of microbial pathogens, increased mortality from spontaneous infections,[69,70] and numerous host defense defects in macrophages and neutrophils.[31,52] In macrophages, all these diverse defects could be corrected by forced expression of PU.1 (Fig. 70-3).[44] Similar defects are present in alveolar macrophages and neutrophils from humans and nonhuman primates with disruption of GM-CSF signaling.[1,2,8,71] *Csf2*^{KO} mice also have systemic immune and inflammatory abnormalities[70] including reduced severity in models of arthritis,[72] an observation that has led to conduct the human trials of GM-CSF signaling disruption as therapy of rheumatoid arthritis.[73,74] These and other studies have led to an emerging understanding of the important roles that GM-CSF plays in the regulation of alveolar macrophage terminal differentiation, the basal functional capacity of circulating neutrophils, and autoimmune and inflammatory diseases.[75]

EPIDEMIOLOGY

Our knowledge of the epidemiology of PAP has improved over the past decade. Results from a national registry study in Japan estimated the incidence and prevalence of autoimmune PAP in Japan to be approximately 0.49 and 6.2 per million in the general population, respectively.[76] A study based on the evaluation of health insurance claims data for 15 million Americans, each associated with a unique anonymizing number, resulted in an estimate of the prevalence of PAP of 7 per million in the general population in the United States.[77] Further, studies in both Japan and the United States have shown that prevalence is proportional to population density.[78,79] In recent reports from specialized clinical centers, the mean age at diagnosis of autoimmune PAP in years (number of patients, country) were 52 (248, Japan),[76] 42 (241, China),[80] 43 (70, Germany),[81] and 40 (81, Italy),[82] although the diagnosis has been made in children as young as 3 years (unpublished). In these reports, the male:female ratio varied from 1.3 to 2.2 overall but was close to 1.0 in nonsmokers. Autoimmune PAP occurs in various racial backgrounds including Asian, Black, and Caucasian, in Hispanic and non-Hispanic individuals, and in wide geographic distribution. Several studies have shown that autoimmune PAP accounts for approximately 89% to 90% of all cases of PAP.[76,78]

A subsequent report from the Japanese registry[61] described 40 cases of secondary PAP identified premortem resulting in a prevalence estimate of approximately 0.3 per million. The incidence and prevalence of congenital PAP are unknown but likely each on the order of 1 to 3 per million in the general population.

CLINICAL FEATURES

Below we consider in detail the clinical, radiographic, laboratory, and bronchoscopic features of PAP. In addition, we review its lung pathology and enumerate the secondary infections associated with the disorder.

■ Presentation

Autoimmune PAP typically presents as progressive dyspnea of insidious onset in previously healthy adults between the ages of 20 and 50 years but has been identified in children as young as 3 years old and in adults as old as 90 years old. In several series, dyspnea occurred in 67% to 94% of patients, followed by cough (23%–66%) and fatigue (49%), whereas fever (4%–11%) and sputum production (1%–4%) were less common.[76,80–82] In the Japanese registry study, one-third of patients were asymptomatic and identified only by mandatory health screening programs and were asymptomatic at presentation (although some developed symptoms subsequently).[76] A history of diffuse pneumonia poorly responsive or unresponsive to antibiotic therapy is usually elicited, and a history should raise the suspicion of PAP. The physical examination is often normal but may include faint inspiratory crackles especially in dependent areas. Cyanosis is occasionally present in more severe cases. Digital clubbing is typically absent in autoimmune PAP. Hereditary PAP presents in remarkably similar fashion but at a mean age of 4.8 ± 1.6 years.[24] Secondary PAP has been reported to present at a median age of 49 years, most frequently accompanied by exertional dyspnea (40% of cases) followed by fever (38% of cases).[61,62] In patients with lung disease associated with abnormal surfactant production, dyspnea is common, crackles may be present, and digital clubbing is not uncommon.

■ Radiographic Appearance

The chest radiograph in primary PAP usually reveals diffuse, bilateral alveolar opacities often with a perihilar predominance resembling the "bat wing" appearance of pulmonary edema but without other signs of left-sided heart failure (Fig. 70-5A, C). The peripheral lung is sometimes spared, resulting in lucency along the diaphragmatic, mediastinal, and peripheral borders. High-resolution computed tomography (HRCT) scanning reveals a characteristic geographic pattern of ground-glass opacification (reflecting the filling of secondary lobules) with superimposed interlobular septal and intralobular thickening, commonly referred to as "crazy paving" (Fig. 70-5B, D), which is characteristic but not diagnostic of PAP.

■ Laboratory Findings

In primary PAP, routine blood counts and chemistries are usually normal in primary PAP except for serum lactate dehydrogenase (LDH), which is increased two- to threefold and correlates well with the degree of functional impairment as determined by physiologic testing and arterial blood gas analysis. A number of biomarkers have been identified in autoimmune PAP including increased serum levels of GM-CSF autoantibody, SP-A, SP-B, SP-D, KL-6, CEA, Cyfra-21-1, cytokeratin 19, and others.[1,76,81–83] Many of these biomarkers are also increased in hereditary PAP.[23–26,60] Importantly, serum GM-CSF is specifically elevated in hereditary PAP but not in autoimmune PAP, which was important in identifying an initial cohort of patients for study (Fig. 70-4).[24] Biomarkers of secondary and congenital PAP have been less well studied.

■ Lung Function

In primary PAP, spirometry and lung volume testing is usually normal or near normal but may show a restrictive pattern of impairment with modest reduction in the vital capacity and total lung capacity (TLC) and a disproportionate reduction of the carbon monoxide diffusing capacity (DL_{CO}). Arterial blood gas analysis in symptomatic patients reveals hypoxia caused by ventilation–perfusion inequality and intrapulmonary shunting, resulting in a widened alveolar–arterial diffusion gradient ($A\text{-}aDO_2$).

■ Bronchoscopic Findings

The bronchoscopic appearance of the airways in primary PAP is normal but white, frothy proteinosis material is occasionally seen.[24,71,81,82] The bronchoalveolar lavage (BAL) fluid is opaque and has a milky or waxy appearance and develops a thick layer of sediment upon standing overnight (Fig. 70-6). The sediment consists of large, acellular, eosinophilic bodies in a diffuse background of granular material that stains with periodic acid–Schiff (Fig. 70-7A). The cellular fraction contains large, foamy macrophages (Fig. 70-7B), smaller monocyte-like macrophages, and lymphocytes with relatively few neutrophils unless infection is also present. Surfactant protein levels are increased, and electron microscopy reveals the presence of lamellar bodies and tubular myelin that are characteristic of surfactant (Fig. 70-2).

■ Lung Pathology

Macroscopically, the cut surface of the lung in autoimmune PAP reveals a patchwork of 2- to 3-cm grayish-yellow regions of consolidation exuding an oily substance. Microscopically, alveoli are filled with a granular eosinophilic material (Fig. 70-7C) that stains strongly for surfactant proteins (Fig. 70-7D).[1] In primary PAP, the alveolar wall and interstitial architecture are usually well preserved (at least early in the disease). Parenchymal lymphocytosis also is present and, in some patients, especially later in the disease course, pulmonary fibrosis can occur. The vasculature appears normal. Electron microscopy reveals alveolar macrophages containing characteristic, concentrically laminated surfactant bodies within the granular material and smaller, single, membrane-delimited, intracytoplasmic vesicles containing esterified cholesterol (a cellular mechanism to protect cells from against an increased cholesterol level). The gross and microscopic appearance of the lung in autoimmune and hereditary PAP are similar.[23–25,28,60] The lung pathology in secondary PAP and congenital PAP varies significantly depending on the disease but is often associated with significant parenchymal pulmonary fibrosis.

■ Secondary Infections

Individuals with autoimmune PAP have an increased risk of infections, which contribute significantly to increased morbidity and

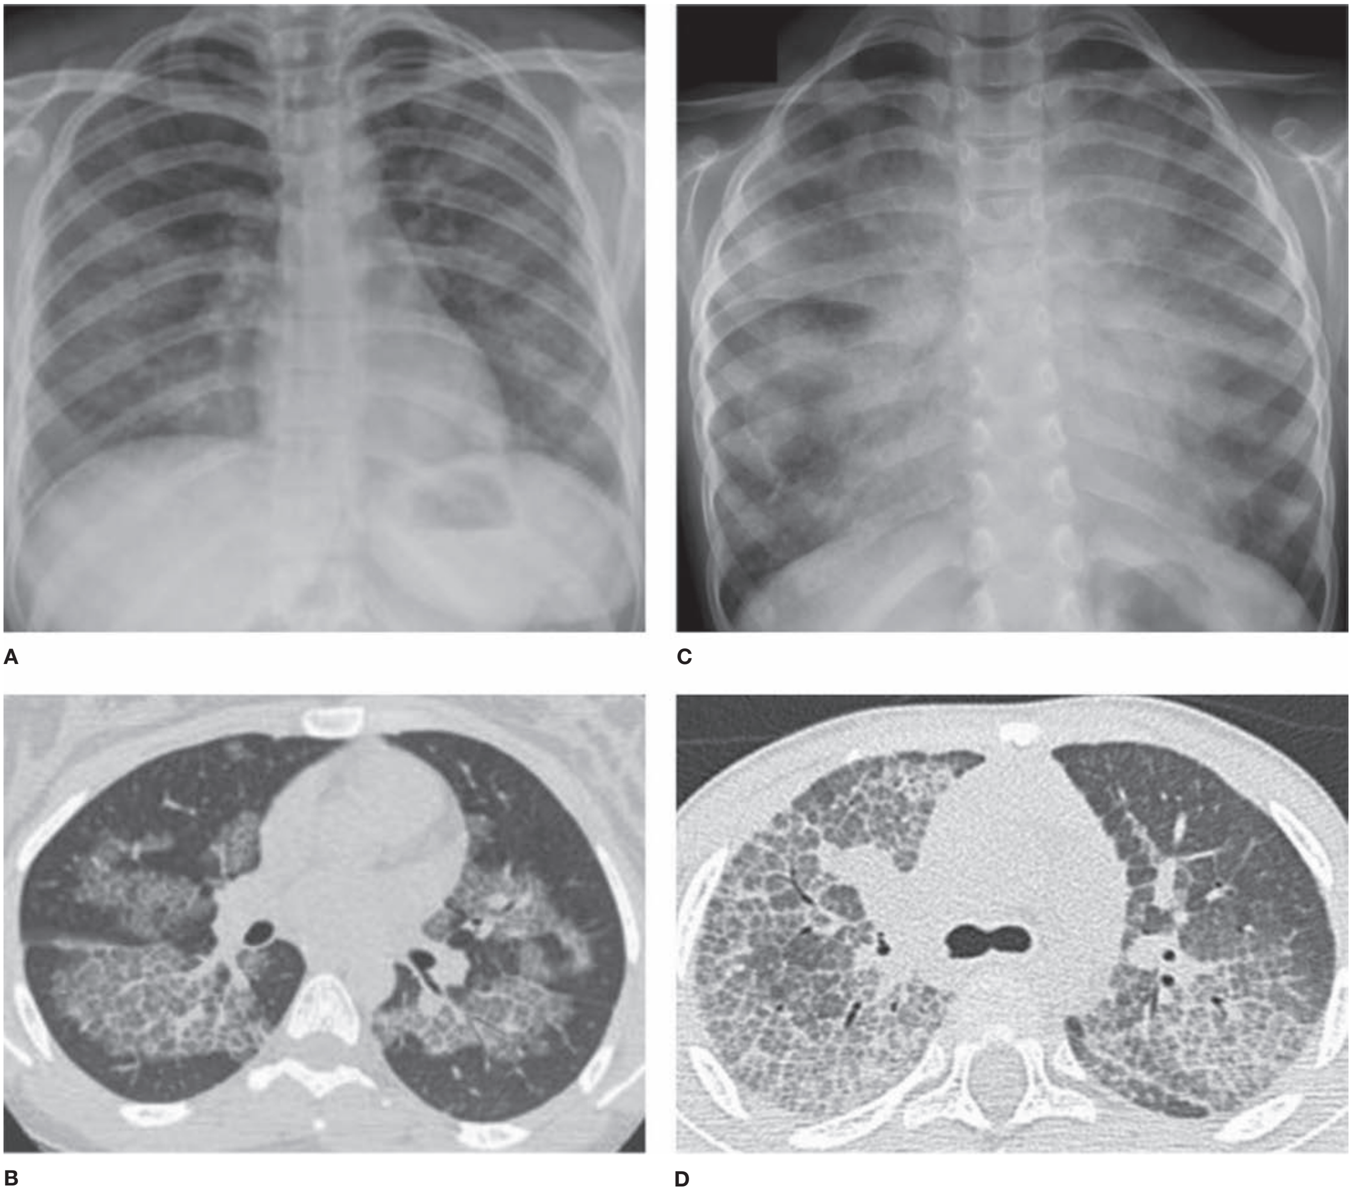

Figure 70-5 Radiographic appearance of primary PAP. **A.** Chest radiograph of a 25-year-old woman with autoimmune PAP. **B.** Corresponding chest HRCT scan. **C.** Chest radiograph of a 6-year-old girl with compound heterozygous *CSF2RA* mutations. **D.** HRCT of a 3-year-old girl with recessive null *CSF2RA* mutations.

mortality.[1,8,83] Although pathogens commonly seen in community- and hospital-acquired lung infections are sometimes identified, opportunistic organisms are often responsible and can include *Nocardia*, *Mycobacterium*, *Aspergillus*, *Cryptococcus*, and others. Infections can occur at both pulmonary and extrapulmonary sites, supporting the concept that a systemic defect in host defense is present secondary to defects in the antimicrobial functions of macrophages and neutrophils.

DIAGNOSIS

While PAP syndrome can be suspected based on historic, physical, and radiographic lung function findings, further studies are needed to exclude other conditions in the differential diagnosis such as hypersensitivity pneumonitis, pulmonary edema, pneumonia, and interstitial lung diseases. Traditionally, transbronchial or surgical lung biopsy have been considered necessary and are commonly used to identify the presence of PAP syndrome. However, none of these histology- and cytology-based approaches including an adequately sized surgical lung biopsy can identify any PAP-causing disease. In contrast, the development and testing of several disease-specific and semispecific biomarkers have been particularly useful. The serum-based GM-CSF autoantibody enzyme-linked immunosorbent assay (Fig. 70-4A) was developed,[84] optimized, and evaluated extensively[8,54,55] and found to have a sensitivity and specificity for a diagnosis of autoimmune PAP approaching 100%.[85] Measurement of GM-CSF signaling in heparinized blood (via STAT5 phosphorylation in leukocytes[23]) also is useful in the differential diagnosis of PAP.

An increase in serum GM-CSF is a sensitive method for diagnosis of hereditary PAP (Fig. 70-4A),[86] which is further supported by a negative GM-CSF autoantibody test and an abnormal STAT5-phosphorylation index test.[23,24]

Secondary PAP can usually be distinguished from primary PAP based on the clinical context and histologic or immunohistochemical evaluation of lung biopsy specimens. Further, PAP disease "mimics," like *Pneumocystis* pneumonia, can be distinguished by special histochemical stains.

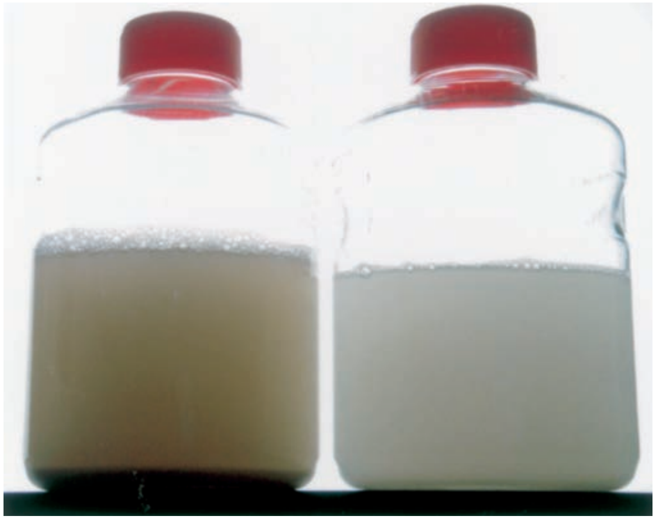

Figure 70-6 Lavage fluid obtained during the whole lung lavage procedure of a patient with autoimmune PAP has a characteristic turbid appearance and a sediment that forms upon standing. The marked opacity and sediment of the fluid observed at the beginning *(left bottle)* shows progressive clearing by the end of the procedure *(right bottle)*.

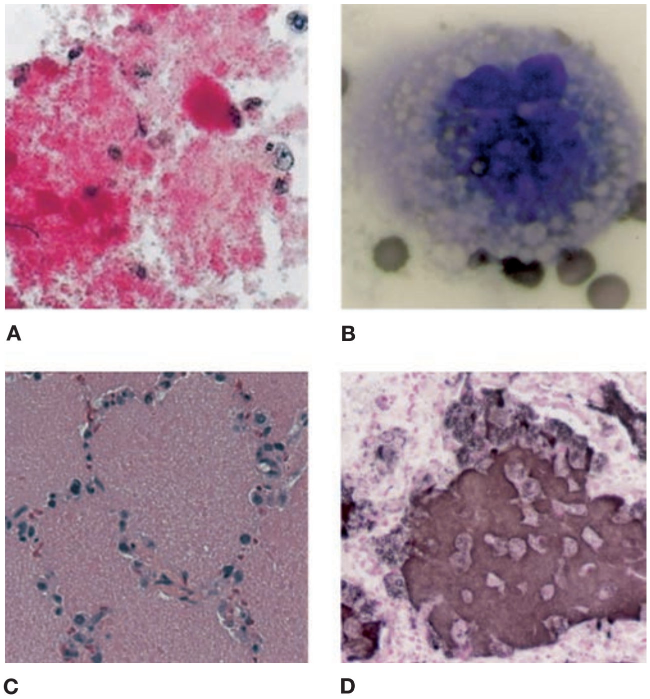

Figure 70-7 Cytologic, pathologic, and immunohistochemical appearance of the lipoproteinaceous material from patients with autoimmune alveolar proteinosis. **A.** Positive periodic acid–Schiff staining of the sediment from bronchoalveolar lavage (×100). **B.** Cytologic appearance of a typical "foamy" alveolar macrophage. **C.** Histopathologic appearance of the lung biopsy specimen from a 10-year-old child with primary PAP. Note the homogeneous staining pattern, normal alveolar wall architecture, and absence of inflammatory cells (H&E, ×200). **D.** Immunohistochemical staining reveals the presence of abundant accumulation of surfactant protein A in a lung biopsy specimen (human anti–surfactant protein A immunostain, ×200).

An important diagnostic clue is that radiographic abnormalities in PAP are often increased out of proportion to the severity suspected on clinical grounds; however, the practical application of this sign requires a high degree of clinical awareness and suspicion.

NATURAL HISTORY

Prospective, longitudinal studies of the natural history of PAP have not been conducted. However, experience from several large retrospective and cross-sectional PAP cohorts (number of patients) at tertiary referral centers in Japan (248), China (241), Germany (70), and Italy (81) have recently been reported.[76,80–82] In these reports, the "time to diagnosis" ranged from 9 to 11 months, which is similar to a report by Seymour and Presneill[83] and less than a recent report estimating this time at 18 months (range, 0.5–13.5 years).[78]

Most patients have slowly progressive disease with mild, persistent symptoms while some have rapidly progressive disease. Spontaneous remission has been reported to occur in 5% to 7% of cases (based on a sample including 399 PAP patients[76,81,82]), confirming a previous estimate of 6% by Seymour and Presneill[83] (based on 410 PAP patients). The consideration of lung disease severity in PAP must account for the degree of surfactant accumulation (which impacts the degree of gas exchange impairment) and on the time-dependent nature of the surfactant accumulation (which impacts the frequency that treatment is required). The variation in the time-dependent rate of surfactant accumulation is seen in autoimmune PAP and hereditary PAP. The latter is a particularly good example since siblings from consanguineous marriages with the same genetic defect in GM-CSF signaling sometimes have widely varying rates of surfactant accumulation and need for therapy.[24]

In the study by Seymour and Presneill, the 5-year survival was 85% without therapy and 95% with whole lung lavage (WLL) therapy.[83] Of deaths attributable to PAP among 303 PAP patients, 47 were due to respiratory failure, 12 were due to overwhelming infection, and 1 was due to cardiac arrest during WLL therapy.[83]

The prognosis of secondary PAP is worse than primary PAP due to linkage with the underlying disease, with an estimated 5-year survival of 20% to 40%.[61,62]

The prognosis of congenital PAP varies, ranging widely from death at birth for SP-B deficiency and some ABCA3 mutations to respiratory insufficiency or failure from interstitial lung disease in adolescence or adulthood for SP-C mutations and some ABCA3 mutations.[4,67]

THERAPY

Therapy of PAP varies by disease. In primary PAP, therapy is required by most but not all patients and is usually initiated when symptoms become limiting. In secondary PAP, treatment is aimed at the underlying clinical condition, although WLL can be effective. In congenital PAP, therapy is generally limited to supportive care, although SP-B deficiency has been treated successfully by lung transplantation.[87]

■ Whole Lung Lavage

WLL is the most widely used therapy of primary PAP[76,80–82] and is still the recommended standard approach. It can be helpful in secondary PAP but has little to no utility in congenital PAP, likely due to the extensive parenchymal derangement present in these patients. In independent cohorts, WLL was used in 54% to 90% of a combined total of 899 patients.[76,80–82] While the indications for initiation of WLL therapy vary widely among centers, some include a histopathologic diagnosis of PAP; PaO_2 <60 mm Hg; A-aDO_2 gradient >40 mm Hg; shunt fraction >10% to 12%; or severe dyspnea at rest or with exercise.[88,89] The technical execution of the WLL procedure itself also varies among centers. WLL requires general anesthesia, separate endotracheal intubation to isolate each lung, and simultaneous mechanical ventilation of one lung while repeatedly filling and draining the other lung with warm saline with or without chest percussion to emulsify and physically remove the alveolar surfactant. Infusion volumes of up to 50 L per lung have been used in adults but may reach diminishing returns above 20–30 L. Other variations include use of extracorporeal or hyperbaric oxygen, and whether the lungs are both treated the same day or different days. While specific therapeutic response criteria have not been defined, most patients experience clinical, physiologic, and radiographic improvement following WLL.[68] Physiologic parameters shown to improve with WLL include an increase in the forced vital capacity (FVC), TLC, $\mathrm{DL}_{\mathrm{CO}}$, and PaO_2 at rest and with exercise, and a decrease in $\mathrm{A\text{-}aDO}_2$ and shunt fraction. WLL improves the 5-year survival from 85% ± 5% to 94% ± 2%.[61] Two studies have reported a duration of response to WLL of 15 months.[60,61] Sequential lobar lavage performed during bronchoscopy as an alternative to WLL has been used for patients deemed unable to tolerate WLL. The use of extracorporeal membrane oxygen therapy is sometimes used in more severely affected PAP patients to permit the use of WLL therapy.

■ Experimental Approaches

Our improved understanding of PAP as a disease driven by reduced GM-CSF–dependent surfactant clearance in alveolar macrophages has stimulated the development of specific pharmacologic therapy. One such strategy is based on augmentation with recombinant human GM-CSF,[90] and multiple clinical trials of subcutaneous or inhaled administration have demonstrated the therapeutic efficacy and safety of GM-CSF therapy of autoimmune PAP.[91–100]

In an early, open-label, nonrandomized study of 39 patients with mild to moderate autoimmune PAP, 62% of the patients receiving inhaled GM-CSF therapy had improvement in the $\mathrm{A\text{-}aDO}_2$ gradient.[96] Several reports have documented the improvement with inhaled GM-CSF by quantitative evaluation of ground-glass opacification (GGO) on chest CT—a measure of the total surfactant burden in PAP.[7,99–102] Two large, phase 3, randomized, double-blind, placebo-controlled clinical trials reported that inhaled GM-CSF improves the clinical manifestations, pulmonary gas exchange, health-related quality of life measures (Saint George's Respiratory Questionnaire score), and GGO.[99,100] To date, none of the studies have identified any important safety concerns, and a current study (IMPALA-2) is underway to gather sufficient data to support the regulatory approval for the use of inhaled GM-CSF as therapy of autoimmune PAP.[91–100] Nevertheless, GM-CSF therapy of autoimmune PAP is still in development and several questions remain unanswered, including the optimal dosage, frequency of administration, and duration of therapy. Data from one of these studies have demonstrated that daily dosing is superior to intermittent daily dosing on alternating weeks. This is consistent with the half-life of GM-CSF–stimulated cholesterol export from alveolar macrophages of 21 h.[6]

Immunotherapy targeting GM-CSF autoantibody–producing cells (rituximab) has been tested as an approach to reduce anti–GM-CSF autoantibody levels;[103–106] however, while encouraging, the number of patients studied is very small and results should be interpreted cautiously.

Statins have been reported to have efficacy in autoimmune PAP related to effects on promoting efflux of cholesterol from alveolar macrophages;[7] however, few patients have been reported to have undergone this treatment approach. Thus, while encouraging, results for this approach should be interpreted cautiously.

A novel *Csf2ra*/*Csf2rb* gene correction approach combined with pulmonary macrophage transplantation (PMT) has shown extraordinary therapeutic efficacy, treatment durability, and improvement in survival/longevity with no safety signal in preclinical studies in validated models of hereditary PAP;[42,43] a clinical trial to test this treatment approach in human patients is planned.

CHAPTER 71

Eosinophilic Lung Diseases

Lauren Cohn
Carolyn L. Rochester
Brian J. Clark

INTRODUCTION

Eosinophils cause lung disease when they release granule proteins, cytokines, arachidonic acid metabolites, superoxide anions, and metalloproteases and other mediators that cause tissue damage, lead to bronchial hyperresponsiveness, and further activate immunologic cascades that enhance inflammation. Pulmonary eosinophilia is a result of enhanced eosinophil development through eosinophil-lineage commitment and maturation in the bone marrow, recruitment into the lung from the circulation, and prolonged eosinophil survival.

Interleukin 5 (IL-5) is the primary cytokine responsible for eosinophilia. While not absolutely essential for eosinophil development, IL-5 enhances eosinophil development and function by stimulating eosinophil differentiation, proliferation, and maturation in the bone marrow, as well as tissue recruitment, activation, and survival. In addition to IL-5, granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, and IL-33 have lesser but important effects on eosinophil differentiation, maturation, and activation.[1] IL-5 acts by binding to IL-5 receptor alpha and signaling through a heterodimeric type 1 cytokine receptor composed of the alpha and beta chain. IL-5 receptors are predominantly expressed on eosinophils, but also on some basophils and B cell precursors.[2] The importance of IL-5 in eosinophilic diseases was tested in animal models using mice with deletion of the IL-5 gene. These animals had marked reductions in eosinophil development, circulation, and recruitment, and absent eosinophil damage in tissues.[1] IL-5 is elevated in the respiratory tract in eosinophilic lung diseases including eosinophilic pneumonias. In human diseases, the importance of IL-5 is highlighted by monoclonal antibody therapies directed against IL-5 and the IL-5 receptor, which have been highly effective in the treatment of pulmonary eosinophilic disorders including asthma and eosinophilic granulomatosis with polyangiitis.

Activated circulating eosinophils bind to inflamed vascular endothelium and migrate into the tissue in response to chemotactic factors including the CCR3 ligands CCL11, CCL24, and CCL26 (eotaxins 1–3), and lipid mediators such as LTB4 and IL-5.[3] High levels of eosinophil chemokines in addition to IL-5 have been demonstrated in the lung and circulation in pulmonary eosinophilic lung diseases.[1,4] Elevation in eosinophil cytokines and chemokines is a common pathway by which pulmonary eosinophilia occurs and, in general, does not differentiate among pulmonary eosinophilic disorders. In each of the pulmonary eosinophilic diseases we review here, the triggers that lead to eosinophilia and eosinophil localization in the lung may be different, but there are shared pathways by which eosinophils develop, migrate, and are activated in the lung to cause damage.

The association between pulmonary infiltrates and eosinophilia was first identified by Loeffler in 1932. It is now recognized that the eosinophilic pneumonias are a heterogeneous group of disorders characterized by varying degrees of pulmonary parenchymal and/or blood eosinophilia. The precise role that eosinophils play in the pathogenesis of the different eosinophilic disorders is not clear. Normally, <2% of the leukocytes in the bronchoalveolar lavage (BAL) are eosinophils. The presence of increased BAL and/or tissue eosinophils, and our knowledge of the biology of eosinophils, does, however, suggest that they play a variety of roles, including initiation, perpetuation, and amplification of tissue inflammation and injury. The different roles of eosinophils in these disorders can be appreciated when comparisons are made between parasitic infections and disorders such as asthma or allergic bronchopulmonary aspergillosis (ABPA). In the former, eosinophils aid in eradicating the infectious pathogen; in the latter, eosinophils accumulate in the lung as a result of immune hypersensitivity, but in both cases, they are prominent mediators of tissue injury. The spectrum of diseases that can be primarily or secondarily associated with blood or pulmonary eosinophilia is shown in Table 71-1. It is beyond the scope of this chapter to discuss each of these disease entities in detail. Instead, discussion will focus on diseases in which eosinophilic infiltration of lung tissue is a characteristic feature.

TABLE 71-1 Diseases Associated with Pulmonary Infiltrates and Eosinophilia

Pulmonary Eosinophilic Syndromes of Known Cause

- Parasitic-induced eosinophilic pneumonias (including Loeffler syndrome)
- Drug- or toxin-induced eosinophilic pneumonias
- Tropical pulmonary eosinophilia
- Allergic bronchopulmonary mycosis

Pulmonary Eosinophilic Syndromes of Unknown Cause

- Idiopathic acute eosinophilic pneumonia
- Chronic eosinophilic pneumonia
- EGPA (allergic granulomatosis and angiitis)
- Idiopathic hypereosinophilic syndrome

Other Lung Diseases Variably Associated with Eosinophilia

- Asthma/allergy
- Bronchocentric granulomatosis
- Bronchiolitis obliterans–organizing pneumonia
- Infections
  - Fungal (esp. coccidioidomycosis, *Aspergillus, Pneumocystis jirovecii*)
  - Tuberculosis
  - Viral
- Interstitial lung disease
  - Idiopathic pulmonary fibrosis
  - Collagen vascular disease associated
  - Sarcoidosis
  - Hypersensitivity pneumonitis
  - Eosinophilic granuloma (pulmonary histiocytosis X)
- Malignancy
  - Non–small-cell cancer of lung
  - Non-Hodgkin lymphoma
  - Myeloblastic leukemia
  - Metastatic disease
- Miscellaneous (e.g., lung transplantation, lung allograft rejection, ulcerative colitis)

TABLE 71-2 Parasitic Infections Associated with Eosinophilic Lung Disease

Helminths Parasites
Intestinal nematodes
Ascaris (lumbricoides and suum)
Ancylostoma duodenale
Necator americanus/Necator brasiliensis
Strongyloides stercoralis and other species
Toxocara canis/Toxocara cati
Trichinella spiralis
Filarial worms
Wuchereria bancrofti
Brugia malayi
Dirofilaria immitis

Most common parasites associated with eosinophilic lung disease. For more detailed listing of pleuropulmonary parasitic infections, see Vijayan VK. Parasitic lung infections. Curr Opin Pulm Med. 2009;15(3):274–282.

PARASITE-INDUCED EOSINOPHILIC LUNG DISEASE

Infections with parasites are commonly associated with pulmonary infiltrates and blood or pulmonary eosinophilia.[5–7] The most common parasites associated with the development of pulmonary eosinophilic syndromes are listed in Table 71-2. In the United States and other Western countries, the parasitic agents most commonly associated with eosinophilic lung diseases are *Ascaris*, *Ancylostoma*, *Toxocara*, and *Strongyloides*.[5] The prevalence of infection with all parasitic organisms varies with geographic location, socioeconomic status, and host immunity. Parasites may invade the lung via direct pulmonary invasion or hematogenous seeding. The site of transit, life cycle, and length of stay of the parasitic agent, and the persistence of the host immune response, are reflected in the human disease.

■ Loeffler Syndrome (Transpulmonary Migration of Helminth Larvae)

Passage of the larvae of helminth parasites through the lungs is the cause of Loeffler syndrome. Loeffler first described this transient, self-limited clinical syndrome characterized by mild respiratory symptoms, peripheral blood eosinophilia, and migratory pulmonary infiltrates. Subsequently, the term *Loeffler syndrome,* or *simple pulmonary eosinophilia,* has been used to define similar cases caused by other parasites, fungal infections, and drug- and toxin-induced pulmonary eosinophilia.[8] In fact, a majority of the original cases were likely caused by the immune response to the parasitic nematode *Ascaris lumbricoides or human roundworm*. *Ascaris* is now uncommon in the United States.

Ascaris lumbricoides and several other helminth parasites including *Ascaris suum*, hookworms (*Ancylostoma duodenale*, *Necator americanus*, *Necator brasiliensis*), *Strongyloides*, *Trichinella spiralis*, and *Toxocara canis* have life cycles in which infecting larvae enter the lungs from the bloodstream and cross into the alveoli.[5,6,9] *Ascaris* is the most common cause of Loeffler syndrome, yet it occurs in only a small minority of *Ascaris*-infected individuals.[10]

Following ingestion of *Ascaris* ova, the larvae hatch within the small intestine, then cross the intestinal wall to enter the splanchnic and ultimately the pulmonary circulation. The larval worms then migrate across pulmonary capillaries into alveoli. The transpulmonary migration of parasite larvae leads to acute inflammation in the lung characterized by eosinophilia that resolves after the larvae pass through. The larvae subsequently migrate into the airways, ascend the large airways, and descend into the alimentary tract into the small bowel where they complete their life cycle.

The hookworm *Ancylostoma* causes a nematodal infection endemic to the southeastern coastal regions of the United States, Mexico, and Central and South America.[5,7] The organism is present in soil contaminated by stool from infected domestic animals. It penetrates human skin most commonly through the feet. This results in the development of the "creeping eruption" lesion—a raised, erythematous, serpiginous, tunnel-like, and often itchy lesion on areas of exposed skin.[11] Loeffler syndrome occurs in up to 50% of cases of "creeping eruption."

Clinical Features

Loeffler syndrome affects people of all ages. Transpulmonary migration of parasitic larvae leads to characteristic symptoms including low-grade fever, nonproductive cough, dyspnea (mild to severe), chest discomfort with coughing or deep breathing, wheezing, and, occasionally, hemoptysis.[5–7] The respiratory manifestations of Loeffler syndrome are usually self-limited, typically resolving in 1 to 2 weeks.

Diagnostic Studies

Laboratory examination of peripheral blood from patients reveals moderate to extreme eosinophilia, which may be at peak levels as respiratory symptoms resolve, and eosinophilia may resolve over several weeks.[5] Expectorated sputum frequently contains eosinophils and/or Charcot–Leyden crystals.[5,7] Radiographic imaging shows transient or migratory, nonsegmental, bilateral, interstitial, and alveolar infiltrates (often peripheral or pleural based).[6] Infiltrates typically clear after several weeks. Pulmonary function testing typically reveals a mild to moderate restrictive ventilatory defect with a reduced diffusing capacity for carbon monoxide ($\mathrm{DL_{CO}}$).

Diagnosis of parasitic infection can be made during the pneumonic stage of the illness by recovery of parasite larvae from respiratory secretions, either sputum or bronchoalveolar lavage, or from a gastric aspirate.[5] In keeping with the life cycle of *Ascaris*, stool examination for ova and parasites is typically negative until 8 weeks after the onset of the respiratory syndrome.[12] Histologic evaluation of lung tissue is not required for confirmation of the diagnosis. When tissue has been obtained, a characteristic and striking eosinophilic infiltration of interstitial and alveolar–capillary units has been noted. Increased numbers of macrophages also have been observed. Tissue necrosis and vasculitis are not features of the disorder. *Ascaris* or hookworm larvae may be identified in the tissue specimen.[5]

Treatment and Prognosis

Bronchodilators, and rarely corticosteroids, may be used for alleviation of pulmonary symptoms, although these symptoms are usually self-limited. In adult cases due to *Ascaris*, treatment with oral mebendazole (100 mg twice a day for 3 days or a single dose of 500 mg)[13] should be given to prevent late GI manifestations of *Ascaris* infestation, which may include malnutrition, diarrhea, abdominal pain, and/or intestinal obstruction. These late GI symptoms begin typically 8 weeks or more after onset of respiratory symptoms. Pyrantel pamoate, albendazole, or ivermectin are alternate treatment options.[5] Since stool specimens are negative for ova and parasites early in the illness, clinical follow-up over a 2- to 3-month period is indicated.

■ Paragonimiasis

Paragonimiasis is caused by lung flukes of the genus *Paragonimus*. Most cases have been reported in Asia due to *P. westermani* as a result of eating raw or undercooked crustaceans or wild boar.[14]

Paragonimiasis has been reported in North America in immigrants from Asia, due to consumption of imported shellfish and, rarely, due to *Paragonimus kellicotti*, the only indigenous species of lung fluke in North America.[15] Once ingested, the *Paragonimus* metacercariae penetrate thru the duodenal wall, cross into the peritoneal cavity, migrate through the diaphragm, and move to the parietal pleura. In the pleural space or lung, the metacercariae mature into adult worms. This trophism for the lung is unique to paragonimiasis species, although in some cases it also invades extrapulmonary sites, most commonly the brain and skin.[16] Adult worms in the lung produce large, thick-shelled eggs (approximately 80 × 50 μm) that are released into the airways, then coughed up and swallowed. The cycle of infection continues when unembryonated eggs from stool or sputum are released into freshwater ecosystems and infect snails followed by crustaceans.

Clinical Features

The clinical syndrome of paragonimiasis reflects the migratory path of the parasite and its interaction with the host immune system. Fever, cough, chest pain, hemoptysis, and peripheral eosinophilia are common and typically begin 2 to 16 weeks after ingesting the infective larvae.[16] Those infected with lower parasite burdens may be asymptomatic or have intermittent cough, fevers, and/or night sweats. Pleuritis is common and caused by worms in the pleural cavity leading to unilateral or bilateral eosinophilic pleural effusion. Chest pain may occur when worms migrate through the pleura and sometimes cause pneumothorax. When worms invade the lung parenchyma, they may cause cough, sputum production, and hemoptysis, and chest imaging may reveal infiltrates. In some cases paragonimiasis may be mistaken for pulmonary tuberculosis.[15]

Diagnostic Testing

Diagnostic testing includes laboratory evaluation, examination of pathologic specimens, and radiographic imaging.

Laboratory Testing Definitive diagnosis of paragonimiasis is made by detection of *Paragonimus* eggs in sputum or stool, but the eggs are not commonly identified. In a series from Japan, eggs were detected only in sputum, BAL fluid, pleural effusion, or feces in 11.7% of cases.[14] Most often the diagnosis relies on serologic testing by ELISA. Elevation of blood eosinophils and IgE were present in 80% of infected patients.[17]

Pathology Pathologic specimens from lung biopsies may contain 1- to 3-mm cysts adjacent to or communicating with airways. Adult flukes may be found in the cystic cavities, whereas the eggs may be found in the lung parenchyma. Granulomatous inflammation with associated eosinophils, eosinophilic microabscesses, and eosinophilic vasculitis are common.[18]

Imaging Chest imaging is abnormal in most cases of pulmonary paragonimiasis. Pleural effusion is the most common radiographic finding. Parenchymal consolidations are typically seen early after lung penetration, whereas peripheral nodules or worm-containing cysts are seen in the late stage after infection. Other CT findings include serpentine worm migration tracks, pneumothorax, and lymphadenopathy.[15,19]

Treatment

All confirmed cases of paragonimiasis should be treated with praziquantel (75 mg/kg per day in 3 doses for 2 days).[13] Treatment failure is rare.

■ Tropical Pulmonary Eosinophilia

Tropical pulmonary eosinophilia (TPE) is a rare manifestation of human filarial infections, mostly from *Wuchereria bancrofti* and *Brugia malayi.* TPE represents a distinct immune response to the microfilaria in the lung that occurs in less than 1% of those infected. TPE is most prominent in India, Africa, and Southeast Asia, but it may be seen worldwide in filarial-endemic regions.[5,6,20] Disease may also be present in nonendemic regions among immigrants or travelers.[20,21] TPE is approximately four times more common in men, and most patients with TPE manifest the disease between the age of 25 and 40 years, although children and older adults also may be affected.[5,20] There is no known seasonal or genetic propensity to this disease, and it remains unclear why only such a small percentage of patients with filarial infection develop TPE.

Clinical Features

Infected larvae are typically introduced into humans by a mosquito bite and subsequently develop into adult worms that inhabit the lymphatics for many years, where they typically do not cause any symptoms. Pregnant females discharge microfilariae, some of which enter into the bloodstream and are trapped in the pulmonary vasculature. In TPE the release of antigens from degenerating microfilariae in the pulmonary vessels causes an intense pulmonary and systemic inflammatory response characterized by parasite-specific antibodies and eosinophilia in peripheral blood and within the lung.[5,7,20] The immune response to filaria is complex and involves many facets of the immune system, but it remains unknown what drives susceptibility to development of TPE and why such a small percentage of infected patients develop pulmonary disease.[22]

TPE may develop months to years after the filarial infection and is characterized by fevers, malaise, anorexia, weight loss, paroxysmal dry cough with dyspnea or wheezing, marked peripheral blood eosinophilia, and spontaneous resolution over several weeks.[5,23] The most common distinguishing symptom of TPE is spasmodic cough that usually occurs at night.[20] Dyspnea and wheezing, which can be severe, are common, and the clinical presentation may resemble status asthmaticus. Chest pain, muscle tenderness, and cardiac, pericardial, and CNS involvement also have been reported. Rarely, patients remain asymptomatic. Physical examination of patients with TPE is notable for coarse rales or rhonchi and wheezing, although no abnormalities are found in approximately 20% of patients.[20] Generalized lymphadenopathy and hepatosplenomegaly, pericarditis, and musculoskeletal or CNS manifestations may be present, but they are less common in adults than in children.[5,20]

Diagnostic Testing

Important elements in the clinical evaluation of suspected tropical pulmonary eosinophilia include laboratory testing, pulmonary function testing, examination of pathologic specimens, radiographic imaging, and application of diagnostic criteria.

Laboratory Testing Microfilariae are not detected in blood or sputum, nor are filarial ova identified in the stool or urine.[5] In contrast, microfilariae have been identified in tissue from lung and lymph nodes, especially when lymphadenopathy is present. High titers of filarial-specific IgE and IgG confirm an infection,[6,7] but in endemic regions this is not diagnostic due to the high prevalence of filarial infection. Other diagnostic tests are, therefore, essential to aid in diagnosis of TPE. Elevated eosinophils in the blood and lung are typical of TPE. Peripheral blood eosinophils may be extremely high, often more than 3000 eosinophils per cubic millimeter and up to 90% of the leukocyte differential, and may persist for several weeks, although the degree of eosinophilia generally does not correlate well with clinical disease severity or radiographic findings.[5,7,20] Blood eosinophils may show signs of activation including degranulation and increased cytoplasmic vacuoles.[20] Eosinophils are also elevated in the sputum and BAL. Eosinophils may make up to 50% of the leukocyte differential in the BAL.[5,7] Pleural fluid, when present, also is eosinophilic.[5] Total serum IgE is usually elevated (>1000 U/mL), and hypergammaglobulinemia results from polyclonal activation of B cells.[5] BAL and pleural fluid contain elevated levels of total IgE, IgM, IgG, and filarial-specific IgE.[5,7] Serum α1-antitrypsin is reduced and returns to normal with treatment.[5,24]

Lung Function Testing Pulmonary function test findings vary with the duration of disease. An obstructive ventilatory defect was observed in up to 30% of patients, particularly when symptoms were present for less than 1 month. Typical of long-standing disease is a restrictive ventilatory defect and reduced $D_{L_{CO}}$, with or without a concomitant obstructive defect.[5–7] Mild arterial hypoxemia may be present.[20]

Pathology In the first 2 weeks after symptoms begin, lung tissue is characterized by histiocytic inflammation in the alveolar, interstitial, peribronchial, and perivascular spaces, with preservation of lung architecture.[5,20] Tiny nodules may be palpable within the lung tissue. One to three months after symptom onset, eosinophilic infiltration with eosinophilic bronchopneumonia and microabscesses is present in lungs of untreated patients. Degenerating microfilariae may be present within the center of the microabscesses, and some destruction of alveolar walls may be evident. Local bronchial walls are also edematous and inflamed, with evidence of epithelial disruption. Long-standing untreated disease is associated with the presence of chronic mixed-cell inflammation (histiocytes, eosinophils, and lymphocytes) in a nodular pattern and the development of pulmonary fibrosis.[5,20] Foreign body–type granulomatous lesions are often present. Lymph node biopsies may reveal degenerating microfilariae or adult worms, surrounded by aggregates of eosinophils, their granule products, and giant cells.

Imaging The chest radiograph may be normal at the time of presentation in up to 20% of patients.[5,6,20] More commonly in TPE, there are ill-defined, diffuse reticulonodular infiltrates primarily affecting the mid to lower lung fields.[5,6,20] Bronchovascular markings may be prominent, and hilar adenopathy and pleural effusions have occasionally been reported.[5,6,20] In rare cases where *Dirofilaria* is the causative agent, the chest radiograph may reveal solitary or multiple nodules thought to represent infarcts caused by parasitic emboli. CT scans often show widespread, ill-defined bronchocentric nodules, mediastinal adenopathy, bronchiectasis, and areas of calcification.[25]

Diagnostic Criteria The diagnosis of TPE is usually established on the basis of the clinical and laboratory findings described earlier including pertinent exposure history. Lung or other tissue biopsies are not typically required. The diagnostic criteria for TPE are summarized in Table 71-3.[20] Biopsy of enlarged lymph nodes (e.g., scalene) may assist in establishing the diagnosis in some cases. A rapid treatment response may provide confirmatory evidence that the correct diagnosis has been made. The differential diagnosis includes Loeffler syndrome, CEP, ABPA, drug reactions, other parasitic infections, hypereosinophilic syndrome (HES), and lymphangitic spread of carcinoma. In nonendemic areas, the disease may also masquerade as asthma, atypical pneumonia, sarcoidosis, EGPA, granulomatosis with polyangiitis, or tuberculosis (TB). Diagnosis in nonendemic regions is often delayed, and a careful review of travel history and a high index of suspicion are necessary to prompt the diagnosis.

TABLE 71-3 Diagnostic Criteria for Tropical Pulmonary Eosinophilia

Relevant exposure in endemic area
Paroxysmal nocturnal cough, dyspnea
Infiltrate on chest radiograph
Leukocytosis with eosinophilia
Elevated serum IgE
Elevated serum antifilarial IgE, IgG (*W. bancrofti*, *B. malayi*)
Clinical improvement with diethylcarbamazine treatment

Treatment and Prognosis

Diethylcarbamazine, a piperazine derivative, is the therapy of choice for TPE, typically at a dose of 6 mg/kg/d in 3 doses for 14 or 21 days.[5] Diethylcarbamazine acts by both direct and indirect mechanisms. It is directly filaricidal to both adult worms and microfilariae. A marked clinical improvement and decrease in eosinophil count usually occurs in the first 7 to 14 days of therapy. Clinical improvement following diethylcarbamazine treatment has been correlated temporally with the resolution of eosinophilic alveolitis. In addition, improvement in pulmonary function, reduction in BAL eosinophilia, a decrease in total and filarial-specific IgE and IgG, increase in serum α1-antitrypsin levels, and radiographic clearing generally occur within 1 to 4 weeks of treatment.[5]

Patients treated with diethylcarbamazine generally have a benign course, and diethylcarbamazine therapy for 3 weeks is curative in most patients. However, acute relapses related to reinfection or release of microfilaria from persistent adult worms occur in up to 20% of patients.[5] Patients with low α1-antitrypsin levels after initial treatment may be at greater risk of relapse.[24] Patients who experience acute relapses often respond to additional treatment with diethylcarbamazine at higher doses of 2 to 4 mg/kg three times a day for 21 to 30 days. Persistent clinical symptoms have been reported over 2- to 5-year follow-up periods in up to 13% of patients with TPE treated with a standard course of therapy. If left untreated, TPE usually persists for weeks to months. Disease may remit spontaneously, but it commonly recurs within months to years. Mild, chronic inflammation may persist and lead to chronic interstitial lung disease with persistent respiratory symptoms, radiographic findings, and hematologic and serologic abnormalities.[20,21,26]

Strongyloidiasis *Strongyloides* infection is endemic in tropical and subtropical regions including rural areas in southeastern United States.[6,27] In soil contaminated by human feces, the larvae enter through bare skin. Acute strongyloidiasis may rarely cause Loeffler syndrome about 1 week after infection as larvae migrate from the skin into the bloodstream, then through the lungs.

Clinical Features It is more typical to have absent pulmonary complaints, but mild GI symptoms may occur about 3 weeks after infection when the parasite becomes established in the small intestine. In the intestines, the adult worms produce larvae that initiate repeated cycles of endogenous infection known as *autoinfection*. The larvae then re-enter the colonic wall or perianal skin and the bloodstream. This cycle can persist for many years, as the intact immune system keeps the process in check but cannot eliminate the parasite.[27,28]

Chronic strongyloidiasis is typically asymptomatic or characterized by mild pulmonary, GI, and/or skin symptoms. Repeated cycles of reinfection and migration of larvae through the lungs can lead to fever and pneumonias, often mistaken as bacterial pneumonias. Chronic strongyloidiasis is well-known for causing recurrent asthma-like symptoms, and because of the cycles of reinfection/migration, patients may be diagnosed with frequent asthma exacerbations. Strongyloidiasis is more common in patients with underlying lung disease, making diagnosis of parasitic infection more complex.[28] Immunosuppression with systemic corticosteroids to treat asthma or COPD has the potential risk of worsening of nondisseminated infection.[28]

The hyperinfection syndrome results from accelerated autoinfection leading to widespread dissemination of the parasite in immunocompromised patients with defects in cell-mediated immunity (such as with corticosteroid use; in lymphoma, HIV, or human T-lymphotropic virus type 1 [HTLV-1] infection; and in transplant recipients).[27] Respiratory manifestations include cough, dyspnea, chronic bronchitis, wheezing, hemoptysis, and patchy pulmonary infiltrates, in association with blood eosinophilia. In severe *Strongyloides* hyperinfection with dissemination, acute respiratory distress syndrome (ARDS) has been reported.[27,28] GI manifestations are common, including abdominal pain, diarrhea, paralytic ileus, nausea and vomiting, bowel perforation, and secondary sepsis from gram-negative bacteria. Central nervous system (CNS) manifestations such as meningitis are also possible. Mortality in the hyperinfection syndrome can reach 80% and is typically due to gram-negative bacterial sepsis.[29]

Diagnostic Testing Elements of the diagnostic evaluation of Strongyloides infection are discussed below.

Laboratory Testing Definitive diagnosis of chronic *Strongyloides* infection is difficult and requires direct parasite detection or culture of eggs or larvae from stool or other fluids. Parasite culture and identification is of low sensitivity due to the intermittent release of eggs by the adult female worm.[27] In contrast, in hyperinfection syndrome with dissemination, large numbers of larvae are released in stool, BAL, and other fluids, and diagnosis is feasible. Molecular detection using nucleic acid amplification methods, such as PCR, have greater sensitivity than direct identification techniques, but in asymptomatic patients with low larval levels, sensitivity is still not high.[30] Serologic assays, such as ELISA, to detect anti-*Strongyloides* IgG are commonly used to help to establish a diagnosis. These methods, though, have limitations including cross-reactivity with other parasites and cannot distinguish between early or late, acute or chronic disease.[30] Patients at risk for *Strongyloides* hyperinfection syndrome should be screened for the parasite prior to initiation of immunosuppressive therapy.[6] In general, the high negative predictive value of serologic testing is useful to exclude *Strongyloides stercoralis* infection.

During the migratory phase, when the microfilariae move from pulmonary capillaries into the alveoli, there is commonly peripheral eosinophilia and elevated serum IgE.[28] In this phase, there may be pulmonary infiltrates with eosinophilia, or asthma without pulmonary infiltrates. Peripheral blood eosinophilia may be absent in up to one-third of *Strongyloides*-infected patients, and eosinophilia is seen only in a minority of hyperinfection cases.[27,31]

Imaging Radiologic findings in strongyloidiasis include ground-glass opacities, septal thickening, consolidations, and patchy migratory infiltrates. Miliary pulmonary micronodules are less common. Secondary bacterial infections and hemorrhage may often overlap the other features. Diffuse bilateral infiltrates in ARDS also may be observed.[19]

Treatment and Prognosis Ivermectin is the treatment of choice and is used at 200 μg/kg for 2 days for the treatment of uncomplicated disease. Hyperinfection syndrome associated with *Strongyloides*, which can have severe consequences, should be treated urgently and therapy should be continued for a minimum of 2 weeks after stool samples test negative for larvae. A reduction in immunosuppressive therapy should be considered.[27]

■ Visceral Larvae Migrans

Systemic infection with the intestinal roundworm of the dog, *Toxocara canis*, is the predominant cause of visceral larva migrans (VLM). *Toxocara catis* and *Ascaris suum* are less-common causes of VLM. VLM occurs worldwide, particularly in tropical climates. Humans are accidental hosts of *Toxocara* when infective eggs are ingested in soil contaminated with dog feces or when raw animal products are consumed. Once ingested, the eggs hatch and penetrate the intestinal wall and disseminate in the circulation to various tissues including lungs, liver, eyes, heart, brain and muscle. The larvae are unable to grow or replicate in the tissues, but the host inflammatory response to the larvae can cause local damage.

Clinical Features

VLM is characterized by hepatomegaly, leukocytosis, fever, hypergammaglobulinemia, and persistent blood eosinophilia.[32] Pulmonary involvement of varying severities occurs in 20% to 80% of cases and includes mild cough, wheezing, bronchiolitis, asthma, and pneumonitis. Because the disease most commonly affects young children, a high degree of clinical suspicion is necessary to establish the diagnosis in adults. Diagnosis is suspected when there is history of geophagia or ingestion of raw animal parts along with allergic symptoms.

Diagnostic Testing

Laboratory evaluation reveals peripheral blood and BAL eosinophilia and elevated serum levels of IgE. Eosinophilia may persist for many months, even in self-limited disease.[5] ELISA testing for *Toxocara* larval antigens is diagnostic. CT imaging most frequently shows multiple, bilateral, peripheral nodules, some with a halo sign, or ground-glass opacities.[33]

Treatment and Prognosis

Most patients have mild, self-limited disease and do not require antihelminthic treatment. Symptomatic patients are typically treated with albendazole 400 mg daily for 5 days or mebendazole.[13] Antihistamines and sometimes corticosteroids may speed recovery in patients who are severely ill.

ACUTE EOSINOPHILIC PNEUMONIA

Initial reports of acute eosinophilic pneumonia (AEP) described a respiratory illness of unknown cause,[34] but over the past four decades, numerous studies have shown that a majority of cases are caused by inhaled exposures, most commonly tobacco smoke.[34–39] Although seen in patients of both genders and in any age group, AEP tends to occur in patients between the age of 20 and 40[35,40,41] and is more common in men.[34] AEP occurs commonly in previously healthy people and represents an acute inflammatory reaction to an inhaled agent.[37,39] Many cases have been reported in patients who have recently commenced smoking cigarettes,[38,39,42,43] vaping,[44,45] used flavored tobacco products,[46] or had other changes in smoking habits. The disease may recur when former smokers resume smoking.[47,48] Overall, up to 70% of patients with AEP have a history of smoking.[35,49] Similar cases have been reported in persons with a history of chronic myelogenous leukemia, hematopoietic stem cell transplantation, or HIV infection.[50–52] In addition, cases have been reported in persons treated with venlafaxine,[53] minocycline,[35] daptomycin,[54,55] and several other drugs.[35] It has also been reported among persons who have been involved in activities with unusual exposures, including exposure to dust from the World Trade Center collapse in New York City,[56] during military deployment in Iraq,[57] cave exploration, gasoline tank cleaning, plant repotting, woodpile moving, and indoor renovations.[35,58] AEP has also been seen following inhalation of cocaine or heroin,[59,60] and in association with H1N1 influenza infection.[61,62] Although none of the patients in the original reported series had atopy or asthma, cases have since been described in persons with a history of atopy. No definite seasonal variation has been identified.

■ Clinical Features

AEP presents as an acute illness with dyspnea, fever, nonproductive cough, tachypnea, pleuritic chest pain, hypoxemia (arterial Pa_{O_2} under 60 mm Hg), and sometimes with myalgias.[34,35,49] Symptom duration is typically less than 7 days, although longer courses of up to 30 days have been described.[61] Patients usually have diffuse inspiratory crackles on chest auscultation, wheezing may be present, and rapid progression from mild dyspnea to overt respiratory failure requiring mechanical ventilation is common.[35,38,57] Early clinical features may be mistaken for community-acquired pneumonia.

Diagnostic Testing

Major components of the diagnostic evaluation of suspected AEP include laboratory testing, pulmonary function testing, imaging, examination of pathologic specimens, and application of diagnostic criteria.

Laboratory Testing

Common findings in AEP include a moderate leukocytosis with left shift,[38] but blood eosinophilia is usually absent at the onset of disease.[35,57] Blood eosinophilia may develop later in the course of the disease and may provide a clue to the diagnosis.[38,63] Serum IgE levels may be moderately elevated.[35,64] The erythrocyte sedimentation rate (ESR) may be elevated as well. Serum levels of thymus and activation-regulated chemokine (TARC)/CCL17 (a ligand for CCR4 on Th2 lymphocytes) may be elevated and may help to distinguish AEP from other causes of acute lung injury (ALI), even in the early phase of disease before blood eosinophilia is present.[65] In contrast, levels of KL-6, a marker for alveolar cell damage, tend to be lower in AEP than in other forms of ALI.[65] If a bronchoscopy is performed, a BAL cell differential should be requested. Eosinophilia (25%–55%) is present in BAL fluid.[39] Increased numbers of lymphocytes (up to 20%) and neutrophils (up to 15%) are commonly also present in BAL fluid in AEP.[66] Pleural effusions are common, and fluid analysis typically reveals a high pH and marked eosinophilia.[36]

Pulmonary Function Testing

Pulmonary function testing is not usually done in AEP due to the acute nature of the disease. Limited data show a restrictive ventilatory defect with a reduced $D_{L_{CO}}$, both of which typically normalize following treatment.[66] An elevated fraction of exhaled nitric oxide (FeNO; e.g., levels >23.5 ppb) may help to distinguish AEP from non-AEP disorders and FeNO levels decreased following corticosteroid treatment.[67]

Imaging

Early in the course of illness, chest radiographs reveal subtle, patchy infiltrates with Kerley B lines.[35,39,68] As disease progresses, CT findings include bilateral patchy areas of ground glass, and areas of consolidation and interlobular septal thickening in a random distribution[39,69] (Fig. 71-1). Thickening of the bronchovascular bundles and lymphadenopathy also are common.[39] Small to moderate bilateral pleural effusions are common (affecting up to 50%–70% of patients).[38]

Pathology

Light microscopic examination of lung tissue reveals prominent eosinophil infiltration in interstitium and/or alveolar spaces, and bronchial walls.[70] The pathologic pattern of diffuse alveolar damage with hyaline membranes and eosinophilic infiltrates should suggest the possibility of AEP. Lymphocytic infiltration of interstitium, type 2 pneumocyte hyperplasia, and intra-alveolar fibrinous exudate also are common. Granulomas, alveolar hemorrhage, and nonnecrotic perivascular inflammation have been reported.[70] Basal lamina damage is unusual.[68] Extrapulmonary involvement is rare.

Diagnostic Criteria

Diagnostic criteria include (1) acute respiratory illness of less than or equal to 1 month duration; (2) pulmonary infiltrates on chest radiography or computed tomography (CT); (3) pulmonary eosinophilia as demonstrated by more than 25% eosinophils in BAL fluid (can be accompanied by variably increased percentages of lymphocytes and neutrophils) or eosinophilic pneumonia on lung biopsy (bronchoscopic or surgical); and (4) absence of known causes of pulmonary eosinophilia, including drugs, toxins, infections, and eosinophilic diseases such as EGPA, HES, and APBA.[39,71]

Using these criteria, idiopathic AEP should be considered in a patient who presents with an acute febrile illness, apparent ALI, or ARDS without a typical antecedent illness and is a diagnosis of exclusion.[36] A history of recent changes in smoking habits should be a flag for possible AEP. A careful search must be undertaken for other causes of pulmonary infiltrates, especially fungal or other infection, and drug or other exposures. Specimens of blood, sputum, stool, BAL, and often transbronchial biopsy specimens should be obtained for stain and culture as well as serologic testing to rule out viral, bacterial, mycobacterial, fungal, and parasitic infection.[35,49]

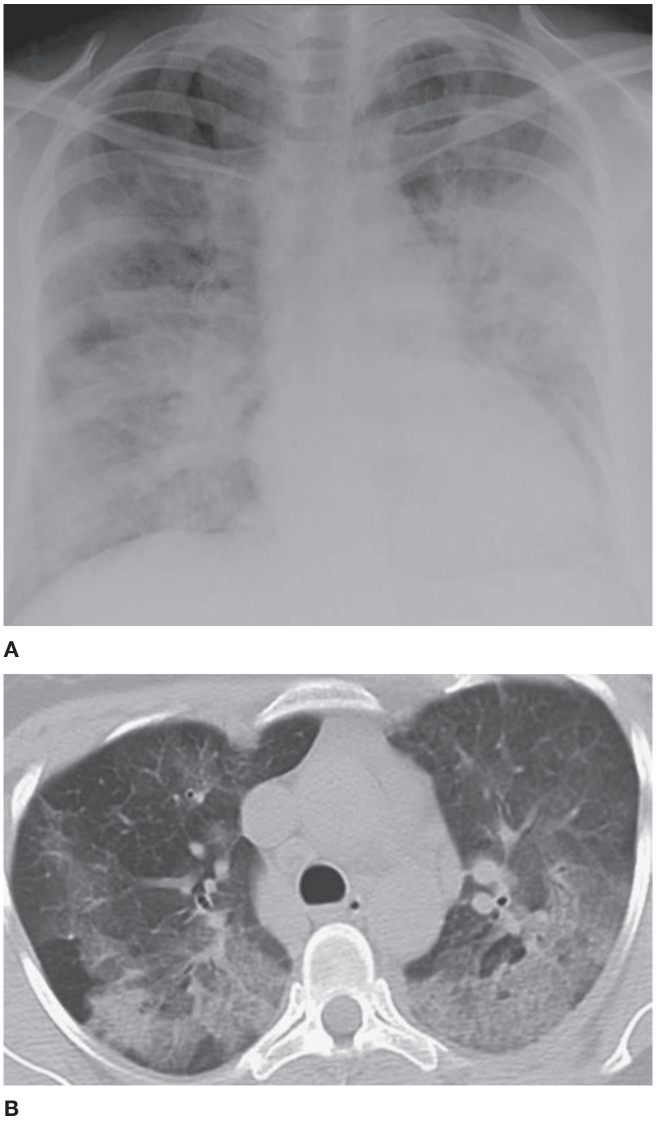

Figure 71-1 Radiographic appearance of idiopathic acute eosinophilic pneumonia (AEP). **A.** Diffuse bilateral alveolar and interstitial infiltrates apparent on chest radiograph. **B.** Diffuse parenchymal ground-glass opacity and consolidation evident on computed tomography scan.

Mechanisms of Disease

The pathogenesis of idiopathic AEP is not defined. The occurrence of cases following environmental inhalational exposures, most commonly cigarette smoke, suggests that these exposures are disease-inciting events that trigger an inflammatory response. It is unknown if the exposure activates the pulmonary innate immune response in an antigen-nonspecific manner and/or if AEP involves an immune response to an (unidentified) specific antigen. One past explanation is that AEP is initiated by a type 1 hypersensitivity reaction involving IgE-mediated mast cell degranulation, although this has not been confirmed.[37] Another hypothesis is that epithelial damage leads to activation of both innate and adaptive immune responses leading to release of type 2 cytokines and chemotactic factors that drive pulmonary eosinophilia.[39]

There is evidence of cell damage in AEP, with elevated BAL levels of damage-associated molecular patterns (DAMPs) including IL-33, uric acid, and ATP.[4] The presence of high IL-33 levels suggests there is epithelial damage,[72] although it is unclear if the release of DAMPs is part of the inciting trigger of AEP or an effect of inflammation. DAMPS can activate eosinophils, and eosinophil-derived granule proteins can cause tissue damage. IL-33 can activate innate lymphocyte type 2 (ILC2) cells and drive the adaptive immune response leading to CD4 Th2 development.[72]

Type 2 cytokines including IL-5, IL-4, and IL-13 have been identified in the BAL of patients with AEP.[4] IL-5 is essential for eosinophilia. In the respiratory tract, eosinophils are recruited to and activated by IL-5. Circulating IL-5 stimulates bone marrow eosinophil production and maturation. IL-13 stimulates production of eosinophil chemotactic factors. Type 2 cytokines are produced largely by lymphoid cells, specifically ILC2 cells and CD4+ Th2 cells. ILC2 cells can be activated rapidly, whereas CD4+ Th2 cells are part of the adaptive immune response and require a period of days to weeks to develop. Eosinophils, mast cells, basophils, gamma-delta T cells, and various other innate immune cells also can produce type 2 cytokines. One day after smoking challenge, an AEP subject had a rise in all leukocyte subsets and IL-4, IL-5, and TNF-α in the BAL, along with a rise in serum IL-5, eotaxin, and other chemokines.[73] The rapid, recall reactivation of the immune response in this patient along with type 2 cytokine release suggests CD4+ Th2 cells are involved in AEP.

Eosinophil chemotactic factors are also present in the BAL of patients with AEP, including the CCR3 ligands CCL11, CCL24, CCL26 (eotaxins 1–3), and CCL13 (MCP-4) and other chemoattractants and lipid mediators such as LTB4.[4] These mediators enhance eosinophil migration into the lung. This elevation of eosinophil chemokines and type 2 cytokines in the BAL is not unique to AEP; it is common in eosinophilic lung diseases, although the levels of all cytokines in AEP were significantly higher when compared with chronic eosinophilic pneumonia.[4]

In summary, eosinophilic lung diseases exhibit common downstream pathways of eosinophil recruitment and activation involving elevation of type 2 cytokines and eosinophil chemokines. The inciting events leading to AEP remain unknown, including the specific agents and triggering mechanisms. AEP is an uncommon disease caused often by a common exposure, cigarette smoke. This suggests that its development involves multiple factors in a predisposed individual, and the triggering factor/event may be different from one individual to another.

Treatment

Treatment of AEP should begin with cessation of exposure to the offending cause if it can be identified. Corticosteroids induce apoptosis of eosinophils and lead to resolution of all eosinophilic pneumonias. Most patients demonstrate rapid, dramatic improvement in response to corticosteroid therapy with abatement of fever and respiratory symptoms within 12 to 48 h and complete resolution of infiltrates, pleural effusion, and pulmonary function impairment usually within 1 month.[34,35,38,49,66] Initial doses of methylprednisolone typically range from 60 to 125 mg administered every 6 h. After resolution of respiratory failure, oral prednisone (in doses of 40–60 mg/d) may be continued for 2 to 4 weeks with a subsequent slow taper over the next several weeks.[35] While corticosteroids are highly effective in reducing eosinophilia, the optimal regimen has not been determined, and while believed to be appropriate therapy, spontaneous disease regression has also been reported.[39,71] In contrast to chronic eosinophilic pneumonia, AEP does not typically relapse after therapy is completed. AEP due to infection requires identification of the pathogen and appropriate antimicrobial therapy.

CHRONIC EOSINOPHILIC PNEUMONIA

Chronic eosinophilic pneumonia (CEP) was first described by Carrington as a clinical entity marked by fevers and radiographic peripheral opacities that rapidly responded to glucocorticoids.[74]

Clinical Features

CEP may develop at any age, but the peak incidence occurs between ages 30 and 45 years.[75–77] Women are affected approximately twice as often as men, and CEP has been reported during pregnancy and following radiation therapy for breast cancer.[78] In one series, asthma was diagnosed in 49% of patients prior to CEP, in 15% contemporaneously, and in 13% after CEP diagnosis.[79] CEP-related asthma is often severe and may lead to fixed airflow obstruction (approximately 10% of patients) despite medical therapy.[79] Approximately one-third to one-half of patients have antecedent atopy, allergic rhinitis, nasal polyps, or urticaria.[75] In addition, a majority of patients with CEP are nonsmokers.

CEP typically has a subacute presentation, with symptoms present for weeks to several months before diagnosis.[75,77] Common presenting complaints include dyspnea, low-grade fevers, malaise, drenching night sweats, and moderate weight loss (10–50 lb).[77,80] Cough, often dry initially and later productive of small amounts of mucoid sputum, is a virtually universal finding.[77] Rhinitis or sinusitis may be present. Two of the nine patients described in Carrington's original series had minor hemoptysis. Patients ultimately develop progressive dyspnea, which may be associated with wheezing in those with asthma. Very rarely, patients with CEP have severe, acute respiratory failure with hypoxemia requiring mechanical ventilation. Rarely, arthralgias, skin rash, diarrhea or colitis, mononeuritis, hepatitis, pericarditis, or unexplained heart failure have been described, raising suspicion that there may be a continuum between CEP and eosinophilic granulomatosis with polyangiitis (EGPA).[77] Cases have been reported in which patients initially diagnosed with CEP later developed EGPA.[81,82]

Diagnostic Testing

Findings on laboratory testing, imaging, pulmonary function testing, and examination of pathologic specimens are discussed below.

Laboratory Testing

Patients with CEP frequently have moderate peripheral blood leukocytosis. The majority (66%–95%) have elevation of blood eosinophils (typically $>1000/\text{mm}^3$) with eosinophils constituting more than 6%, and often up to 20% to 30% of the leukocyte differential.[76,77,83] However, a lack of peripheral blood eosinophilia does not rule out the diagnosis. Normochromic, normocytic anemia and thrombocytosis may be present. Elevation of C-reactive protein and erythrocyte sedimentation rate are common, and IgE levels are elevated in up to one-half of cases.[77] Blood and sputum cultures routinely fail to identify an infectious etiology. Analysis of BAL fluid reveals increased eosinophils, typically accounting for 40% or more of the leukocyte differential, with a range of 12% to 95% reported.[75,77,80,84] Eosinophil

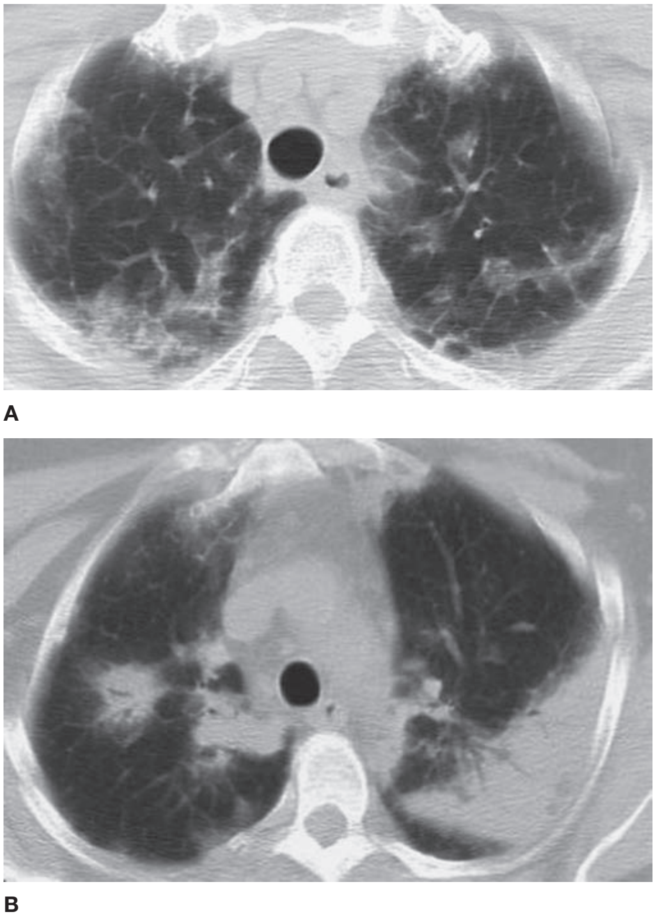

Figure 71-2 Radiographic appearance of chronic eosinophilic pneumonia (CEP). Variable computed tomography appearance of infiltrates in two patients with chronic eosinophilic pneumonia. Peripheral upper lobe–predominant infiltrates may have a ground-glass appearance (**A**) or may appear as regions of dense consolidation or nodular opacity (**B**).

chemoattractant cytokines IL-5, eotaxin, and RANTES (CCL-5) are elevated in BAL fluid of patients with CEP, suggesting that Th2 cells recruit and attract eosinophils to the lung.[77,85]

Imaging

Originally, Carrington et al. described three radiographic features that are characteristic for CEP: (1) peripherally based, progressive dense infiltrates; (2) rapid resolution of infiltrates following corticosteroid treatment, with recurrences in identical locations; and (3) the appearance of infiltrates as the "photographic negative of pulmonary edema."[74,85] The pulmonary infiltrates associated with CEP are typically dense and patchy areas of airspace consolidation with ill-defined margins usually affecting the outer two-thirds of the lung fields (Fig. 71-2). Infiltrates are most commonly bilateral, tend to be located in the mid to upper lung zones, and may mimic loculated pleural fluid. They are frequently nonsegmental, subsegmental, or lobar in distribution. The characteristic "photographic negative of pulmonary edema" occurs in <50% of cases.[86] Pleural effusions and cavitation are rare.[76,87,88] The infiltrates may be migratory in up to 25% of cases. Occasionally, the chest radiograph can be normal.

Findings on CT scan may vary depending on the timing of the CT relative to the onset of symptoms. Typical areas of dense, peripherally located airspace consolidation are found in most cases within the first several weeks of disease onset. Areas of peripheral consolidation often involve the middle and/or upper lung zones, and ground-glass opacities also are common.[76,89–92] Mediastinal adenopathy, which may be evident on conventional chest radiograph, may also be identified on CT scan.[92] Less typical radiographic findings include nodular infiltrates, linear oblique or vertical densities, bronchial wall thickening, pleural effusion, and areas of fibrosis unassociated with anatomic divisions. Streaky bandlike opacities may appear when symptoms have been present for more than 2 months.[89]

Pulmonary Function Testing

Abnormalities in pulmonary function depend on the stage and severity of disease. In the initial stage, prior to treatment with corticosteroids, testing may reveal restrictive, obstructive, or normal physiology.[77] Obstructive ventilatory defects, while more common in patients with a history of asthma, are also encountered in patients without pre-existing asthma. Restrictive physiology may result from eosinophilic infiltration of lung parenchyma. Diffusing capacity may be reduced, and the alveolar–arterial oxygen gradient may be mildly elevated.[77,80]

Pathology

Pulmonary lesions of CEP are characterized by varying degrees of leukocytic infiltration of the alveolar airspaces and alveolar septae. These infiltrates are predominantly eosinophilic, with some associated macrophages, a small to moderate number of lymphocytes, occasional plasma cells, multinucleated giant cells, and an associated fibrinous exudate.[68,74,80] Unlike AEP, the basal lamina may be disrupted, but frank alveolar necrosis is absent.[68] Eosinophilic microabscesses can be found. Focal edema of the capillary endothelium, focal type II epithelial cell hyperplasia, and proteinaceous and fibrinous alveolar exudates also can be appreciated. Histologic evidence of proliferative bronchiolitis obliterans or bronchiolitis obliterans–organizing pneumonia may occur in up to one-third of cases, and a mild, nonnecrotizing microangiitis affecting the small venules may be seen. Biopsy specimens of lymph nodes from patients with intrathoracic lymphadenopathy reveal lymphoid hyperplasia and eosinophil infiltration.[68,74,80]

■ Mechanisms of Disease

The cause of CEP is unknown. No specific genetic predisposition has been identified, although CEP was reported in identical twins, raising the question of a familial tendency toward the disease. An association has been reported between rheumatoid arthritis and CEP, but no clear causal relationship has been identified.[93,94] Although the precise immunopathogenesis of CEP is unknown, evidence suggests that type 2 helper T (Th2) cells have a role in disease pathogenesis. The levels of type 2 cytokines including IL-5, IL-4, and IL-13 and of eosinophil chemoattractants are elevated in the BAL fluid of patients with CEP, albeit at lower levels than typically observed in AEP.[4] Likely, the release of these mediators reflects a common mechanism in eosinophilic pneumonias that drives eosinophil accumulation and activation in the respiratory tract, as reviewed above. The factors that initiate and perpetuate CEP, though, are unclear. Because CEP has a protracted course and high rate of recurrence, this suggests a potential role of Th2 lymphocytes in the pathogenesis of CEP.

■ Diagnostic Criteria

The diagnosis of CEP is based on the presence of compatible clinical characteristics, radiographic findings of peripheral opacities, BAL eosinophilia, and the absence of infection or other known causes of eosinophilic lung disease. The clinical signs and symptoms of CEP are nonspecific, however, and blood eosinophilia and typical radiographic features may be absent in some cases. Transbronchial biopsy, usually performed to rule out other diagnostic entities, may reveal eosinophil and mononuclear cell infiltrates. Surgical lung biopsy is rarely required. Because of the profound responsiveness of CEP to steroid treatment, a therapeutic trial of steroids is often useful in establishing the diagnosis. Failure to document rapid clinical improvement should alert the clinician to consider other diagnoses. The differential diagnosis of CEP includes drug-induced eosinophilic pneumonia, infection (especially TB, fungal diseases such as cryptococcosis, and parasitic disease), sarcoidosis, Loeffler syndrome, desquamative interstitial pneumonitis, cryptogenic organizing pneumonia, ABPA, chronic hypersensitivity pneumonitis, acute idiopathic eosinophilic pneumonia, EGPA, and eosinophilic granuloma.

■ Treatment and Prognosis

CEP rarely resolves without therapy and, if left untreated, may result in fibrosis.[95] Corticosteroids are the mainstay of therapy for CEP. Dramatic clinical, radiographic, and physiologic improvements have been documented following steroid treatment in all series reported.[75,77,89] Even patients presenting with severe respiratory failure may respond well to steroid treatment. In most cases, treatment with steroids leads to resolution of fever within 6 h, reduced dyspnea, cough, and blood eosinophilia within 24 to 48 h, resolution of hypoxemia in 2 to 3 days, radiographic improvement within 1 to 2 weeks, complete resolution of symptoms within 2 to 3 weeks, and normalization of the chest radiograph within 2 months.[75,76,80] No comparative studies exist to determine optimum treatment doses or duration of steroids, but a recommended regimen is prednisone 0.5 mg/kg/d (40–60 mg a day) continued until 2 weeks after resolution of symptoms and radiographic abnormalities, generally for 4 to 6 weeks. The dose of prednisone can then be tapered slowly by 0.25 mg/kg/d and then continued for the subsequent 8 weeks. Treatment is usually maintained for at least 3 months and optimally for 6 to 9 months; during this phase prednisone can be decreased by 5 mg every 4 weeks. Shorter courses of prednisone also may be effective.[77]

The prognosis of CEP is generally favorable.[96] In steroid-treated patients, morbidity and mortality directly related to CEP are low. Patients may require 1 to 3 years of initial steroid treatment to control the disease, and up to 50% may require long-term maintenance treatment (2.5–10 mg prednisone a day) to remain disease-free.[75,77] The lowest possible dose of steroid that suppresses disease activity should be used. Inhaled steroids are inadequate monotherapy to treat CEP; however, may have some role in preventing relapses particularly in those with asthma.[79,97,98]

CEP relapses are common, occurring in 50% to 80% of cases when steroids are tapered or discontinued.[75–77,80] Relapses may involve radiographic infiltrates in the same or different anatomic distribution compared with the original disease. Relapsing CEP must be distinguished from the development of new or worsening asthma. No obvious factors exist to identify persons who are likely to relapse or require long-term steroids, although relapses are more common in persons treated initially with a short course (<6 months) of steroids. Relapses should be managed by increasing the prednisone dose to ≥40 mg per day until 2 weeks after symptom control has been achieved, with gradual taper thereafter. The reinstitution of steroids generally leads to improvement, and relapses do not appear to indicate a worse prognosis, increased likelihood of treatment failure, or increased morbidity.

Biologic agents with anti-eosinophilic activity are now a possible steroid-sparing treatment option for disease. The anti–IL-5 antibody mepolizumab has shown some success in treatment of relapses of CEP and has been associated with fewer relapses, improvement in imaging findings, and reduction in oral steroid dosing.[99–101] There is less experience with the anti–IL-5R antibody benralizumab, although there are reports of successful treatment in patients with relapsed disease and as initial therapy in a patient who refused prolonged glucocorticoids.[101–103] Omalizumab, an anti-IgE antibody, has been reported to be a successful steroid-sparing agent in cases of CEP with elevated IgE and allergic sensitization.[104] Dupilumab, an anti–IL-4Rα antibody, has been reported as both a treatment and a cause of CEP.[105,106] Since there can be elevation of blood eosinophils in dupilumab-treated patients, it should not be used to treat CEP until further evidence of benefit is available.[107] The direct, anti-eosinophilic effect of IL-5 pathway drugs, as well as the lack of a requirement for allergic sensation, make them a more universal choice for treatment at this time.

OTHER CHRONIC EOSINOPHILIC LUNG DISEASES

A variety of other chronic eosinophilic lung disorders are considered in detail below.

■ Allergic Bronchopulmonary Aspergillosis (Mycosis)

ABPA is a disorder caused by a hypersensitivity response to inhaled fungal antigens.[108–115] Since the disease is most commonly induced by *Aspergillus* species, it is usually known as ABPA. When induced by non-*Aspergillus* species, the syndrome is called *allergic bronchopulmonary mycosis*.

Clinical Features

ABPA occurs most commonly in immunocompetent patients and complicates 1% to 2% of cases of persistent asthma and 7% to 14% of cases of chronic steroid-dependent asthma, most often among patients in the third to fourth decade of life.[116] ABPA also complicates up to 15% of patients with cystic fibrosis (CF), most often during the teen years.[110,117] Rare cases of ABPA have been reported that lack a history of asthma, but meet the other major diagnostic criteria (summarized in Table 71-4).[118] The diagnosis of ABPA is based on appropriate clinical features in combination with supporting serologic and radiologic findings.[109] The features of ABPA are believed to result from an immunologic reaction to chronic airway colonization by *Aspergillus* (or other relevant fungal species) that includes features of type I, type III, and type IV immune responses.[109] T-helper lymphocytes, neutrophils, eosinophils, genetic susceptibility factors,

TABLE 71-4 Diagnostic Criteria for ABPA (ISHAM Working Group)[127]

Predisposing conditions
Asthma
Cystic fibrosis
Obligatory criteria *(both should be present)*
Type I *Aspergillus* skin test positive (immediate cutaneous hypersensitivity to *Aspergillus* antigen) or elevated IgE levels against *Aspergillus fumigatus*
Elevated total IgE levels (>1000 IU/mL)[a]
Other criteria *(at least two of three should be present)*
Presence of precipitating or IgG antibodies against *Aspergillus fumigatus* in serum
Radiographic pulmonary opacities consistent with ABPA[b]
Total eosinophil count >500 cells/µL in steroid-naïve patients (may be historic)

[a] *If the patient meets all other criteria, an IgE value <1000 IU/mL may be acceptable.*

[b] *The chest radiographic features consistent with ABPA may be transient (i.e., consolidation, nodules, tram-track opacities, toothpaste/finger-in-glove opacities, fleeting opacities) or permanent (i.e., parallel line and ring shadows, bronchiectasis and pleuropulmonary fibrosis).*

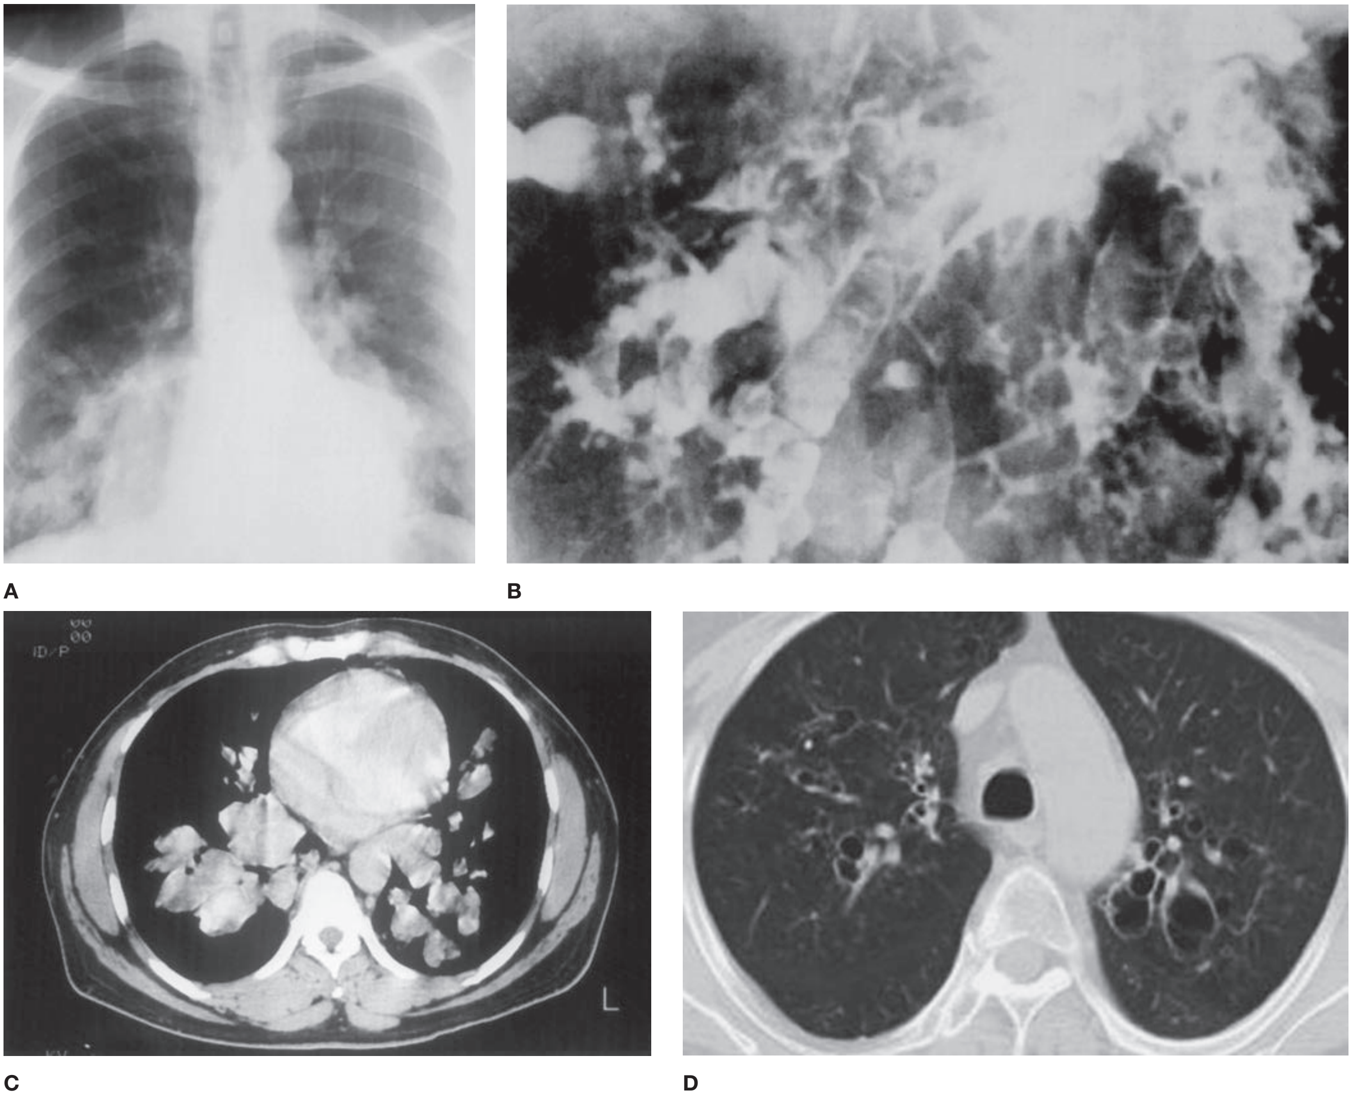

Figure 71-3 Radiographic appearance of allergic bronchopulmonary aspergillosis (ABPA). Extensive infiltrates with tubular configuration and “gloved finger” appearance are present, in this case predominantly in the lower lobes (**A**), the bronchogram (**B**), and computed tomography (CT) of the chest (**C**) reveal extensive proximal bronchiectasis. Extensive mucoid impaction of the bronchi is evident on CT scan (**C**). Central bronchiectasis and tram-track shadows in a patient with ABPA may also be present without mucoid impaction (**D**).

and the fungus itself all likely contribute to the pathogenesis of the disease.[108,119]

Typical symptoms of ABPA include wheeze, cough, dyspnea, and sputum production, with occasional expectoration of brownish/black mucus plugs. Other symptoms may include malaise, myalgias, low-grade fever, chest pain, weight loss, or hemoptysis. The diagnosis of ABPA should be considered in any patient with asthma or CF who experiences frequent exacerbations of respiratory symptoms, and/or the combination of asthma and eosinophilia. Worsening of lung function, steroid dependence, or failure to improve clinically following antibiotic therapy for a suspected bacterial infection suggests the diagnosis in patients with CF.[117,120]

Diagnostic Testing

Diagnostic evaluation includes radiographic imaging, examination of pathologic specimens, and application of diagnostic criteria.

Imaging Typical radiographic manifestations of ABPA include transient, irregular pulmonary infiltrates with a predilection for the upper lobes (Fig. 71-3).[90,121] Other common radiographic features include “finger-in-glove opacities,” “tramline shadows,” “parallel lines,” “toothpaste shadows,” “ring shadows,” and lobar consolidation (Fig. 71-3). These findings result from bronchial and bronchiolar wall inflammation, edema, and remodeling, and from mucoid impaction of the bronchi with or without parenchymal involvement. As noted, central (proximal) bronchiectasis, another characteristic radiographic manifestation of ABPA, occurs in many but not all patients. The presence of high-attenuation mucus on HRCT may be a marker for disease severity.[122]

Pathology ABPA is not typically diagnosed by tissue sampling. Nevertheless, histopathologic findings of ABPA include intense bronchocentric inflammation with eosinophils, lymphocytes, plasma cells, and monocytes, bronchocentric granulomatosis, and mucoid impaction of bronchi.[117,123] Fungal hyphae are typically present in mucus plugs without bronchial tissue invasion. The histologic findings may vary in differing parts of the lung and in different stages of the disease.

Diagnostic Criteria Originally, Greenberger and Patterson proposed five minimal essential criteria needed to establish the diagnosis, including (1) asthma, (2) positive immediate hypersensitivity skin test to *Aspergillus,* (3) total IgE greater than 1000 ng/mL (or >417 IU/mL), (4) elevated serum anti–*Aspergillus fumigatus* (AF) IgE and IgG (>2-fold greater than for asthmatic controls), and (5) serum precipitins to AF or other relevant fungus.[124] These features, as well as a history of current or previous pulmonary infiltrates and/or central bronchiectasis evident on high-resolution CT scan (HRCT) and peripheral blood eosinophils (∼10,000 cells/mL), constituted the initial diagnostic criteria of ABPA.[108,111,123–126] An updated criterion adopted by the International Society for Human and Animal Mycology (ISHAM) working group provides a more simplified approach (Table 71-4). These require a predisposing condition (asthma or cystic fibrosis). Obligatory criteria are skin test positivity to aspergillus or elevated IgE against *Aspergillus* and an IgE above 1000 IU/mL. Additional criteria, of which two are required, include the presence of precipitating or IgG antibodies against aspergillus, thoracic imaging findings consistent with ABPA, and peripheral blood eosinophils >500 cells/μL.[127]

Five clinical stages of ABPA have been described: acute illness (stage 1); remission (stage II); exacerbation (stage III); steroid-dependent asthma (stage IV); and fibrotic lung disease (stage V).[109,110,124] Two variants of ABPA have been recognized: seropositive ABPA (ABPA-S), wherein the preceding essential criteria are met and there is no evidence of central bronchiectasis; and ABPA with central bronchiectasis (ABPA-CB) in which CB also is present.[110,128] It is unclear whether ABPA-S is an earlier stage of disease that precedes ABPA-CB or whether it is a milder form of the disease. The differential diagnosis of ABPA is broad, and in addition to other pulmonary eosinophilic disorders, includes asthma with fungal sensitization without ABPA, refractory asthma without fungal sensitization, *Aspergillus* bronchitis, and other nonfungal infectious bronchitis or pneumonia. ABPA often goes unrecognized due to overlap of clinical features with these disorders. ABPA may also be challenging to recognize due to the varying clinical presentations at different stages of disease.

Treatment and Prognosis

The goals of treatment are to control symptoms, preserve normal lung function, and prevent exacerbations and disease progression. Early recognition and aggressive treatment are essential to prevent development of permanent airway remodeling, bronchiectasis, and pulmonary fibrosis.[110] Systemic corticosteroids, with careful patient monitoring of clinical symptoms, IgE levels, and chest radiograph, are the mainstay of therapy.[122,129,130] Corticosteroid doses that reduce IgE levels by at least half of acute stage levels within 6 to 8 weeks and induce clearing of radiographic infiltrates should be used to control the disease. These doses are typically higher than those needed to control symptoms alone. The recommended initial prednisone dose is 0.5 mg/kg/d for 2 weeks followed by every-other-day dosing for 6 to 12 weeks, followed by a gradual taper of 5 to 10 mg every 2 weeks over 3 to 6 months.[110] Children with CF may require higher doses and/or longer duration of treatment. Total serum IgE levels should be measured at the time of diagnosis, at 4 and 8 weeks, and every 2 months thereafter for 1 year.

Treatment with the antifungal agent itraconazole can also help control the symptoms and immunologic features and exacerbations of the disease and may enable reduction of the systemic corticosteroid dose.[131–134] Voriconazole may be a suitable alternate antifungal agent, and a single nonblind trial showed a high response rate.[135–137] In case series, the anti-IgE antibody omalizumab helped to control ABPA in steroid-dependent patients who failed itraconazole treatment.[138–141] The anti-IL5 antibody mepolizumab led to reduction in systemic glucocorticoid dose, number of disease exacerbations, and improved quality of life in a case series of 20 patients with ABPA and asthma, but it has not been studied in a controlled fashion.[100] In case reports, patients with ABPA have had positive responses to benralizumab (anti–IL-5 receptor), including one patient who did not respond to omalizumab.[103,142] Dupilumab (anti–IL-4 receptor alpha) was effective therapy in a case series of three patients, leading to reductions in systemic glucocorticoid doses, but with the notable side effect of hypereosinophilia in two of the patients.[143] Additional studies to evaluate the efficacy of biologic therapies in ABPA are ongoing. Bronchodilators and antibiotics help control bronchospasm and secondary respiratory infections. Inhaled corticosteroids alone are inadequate to treat acute episodes of ABPA, yet high doses of inhaled corticosteroids are standard treatment to control disease. Patients should be monitored with at least yearly spirometry and assessed for concurrent gastroesophageal reflux, rhinosinusitis, or environmental mold exposures.[110]

■ Eosinophilic Granulomatosis with Polyangiitis

In 1939, Rackemann and Greene reported a subgroup of patients with polyarteritis nodosa and concomitant allergic disease. The histopathology and clinical features associated with this disease entity were first described in 1951 by Churg and Strauss, who reported a form of necrotizing vasculitis in several organs associated with eosinophilic tissue inflammation and extravascular granulomas occurring in asthmatics with associated fever and peripheral hypereosinophilia (Churg–Strauss syndrome).[144] This disease entity, now termed *eosinophilic granulomatosis with polyangiitis (EGPA)*, is an uncommon systemic disease.[145–147] An overall prevalence of 10.7 to 13 cases per million inhabitants is estimated among the general population, and up to 64 cases per million persons per year is estimated among patients with a history of asthma.[148] The mean annual incidence has been estimated at 0.5 to 6.8 per million population across various countries.[148] The precise incidence of EGPA is unknown due to uncertainties regarding diagnosis and variable clinical presentation and may be higher than is generally recognized.

Clinical Features

EGPA may occur in patients of any age, but it develops most commonly in patients between the ages of 38 and 50.[75,149,150] It is rare in persons older than age 65, as well as children and adolescents. However, among affected children, it tends to follow a more aggressive clinical course.[151] There is no clear gender predominance.[148,150]

EGPA tends to follow a subacute course with symptoms ranging over months to years. Historically, three distinct clinical phases of the disease have been recognized: the prodromal phase, the eosinophilic phase, and the vasculitic phase.[152,153] The *prodromal phase* has been characterized by “late-onset” (in the second or third decade of life) allergic rhinitis and atopy in persons often lacking a family history of atopy. Severe allergic rhinitis, sinusitis, and drug sensitivity are usually present for 8 to 10 years, and up to 30 years before EGPA disease recognition. Asthma is a feature of EGPA in all cases. It typically precedes the onset of vasculitis by 3 to 6 years.[153] The *eosinophilic phase* is typified by the development of marked peripheral blood eosinophilia and eosinophilic tissue infiltration, most commonly of the lung, GI tract, and skin. The *vasculitic phase* is characterized by vasculitis of the small and medium vessels with vascular and extravascular granulomas. The onset of the vasculitic phase is often heralded by development of constitutional symptoms, including fever, malaise, weight loss, arthralgias, myalgias, and increased allergic or asthmatic symptoms. Although the vasculitis tends to occur several years after the onset of allergic manifestations of the disease, in some cases it develops within months of, or concomitant with, the onset of asthma. A short duration between the onset of asthma and vasculitis has been associated with increased severity of vasculitis. During the vasculitic stage, the asthma symptoms may persist and worsen, or they may diminish. When asthma dissipates, it often flares later in the course of illness and may require prolonged steroid treatment. Not all patients progress sequentially through these phases, and overlap of clinical features of the phases is often present. Although EGPA typically affects multiple organ systems, limited forms of disease also have been described.[148,154] Manifestations in the lungs, heart, skin, and nervous system are most common.

An association between asthma therapies and the development of EGPA has been noted, including leukotriene receptor antagonists (LTRA) and 5-lipoxygenase inhibitors, inhaled glucocorticoids, and omalizumab.[151,155–160] It is uncertain whether these steroid-sparing agents caused the development, or if EGPA was unmasked by the reduction in systemic corticosteroid dosing following initiation of these agents.

Lung involvement occurs in nearly all patients with EGPA.[148] Most of the respiratory manifestations of EGPA occur in the prodromal and eosinophilic phases of the disease. All patients have asthma at some point in the illness. Upper airway allergic disease, including sinusitis, rhinitis, and polyposis, is seen in 75% to 85% of patients and may be the presenting symptom.[75,148] Unlike granulomatosis with polyangiitis (GPA), necrotizing granulomas involving the upper airway are unusual in EGPA. The asthma and upper airway disease usually are long-standing, severe, and often require steroid therapy (systemic, inhaled, intranasal) to maintain control of symptoms.[148] Pulmonary symptoms include dyspnea, cough, and wheezing. Spirometry may reveal an obstructive ventilatory defect.[161]

Cardiac manifestations generally are not evident on initial presentation of EGPA. However, they typically occur during the vasculitic phase of the disease and are a major source of morbidity and the principal cause of death (in up to 50% of cases) from the disorder.[148,149,162] Patients may be asymptomatic. Progressive congestive heart failure (CHF) can occur because of endomyocardial infiltration by eosinophils or ischemic cardiomyopathy resulting from necrotizing vasculitis of the coronary arteries.[75,162,163] Acute pericarditis and cardiac tamponade have been reported.[164] Constrictive pericarditis may develop over time. Cardiac involvement is more common in patients with EGPA who lack serum ANCA.[165,166] Electrocardiogram, echocardiography, N-terminal pro–brain natriuretic peptide and troponin 1 levels, and/or cardiac MRI are recommended to evaluate patients with suspected EGPA for the presence of cardiac involvement.[148,167] ^{18}FDG/^{13}N ammonia positron emission tomography (PET) imaging also may be useful to identify cardiac involvement in EGPA.

A wide array of neurologic manifestations may develop in EGPA. Mono- or polyneuropathy (most notably mononeuritis multiplex) is common. The common peroneal, ulnar, and internal popliteal nerves are most frequently affected.[148] CNS manifestations occur more rarely and include cranial nerve impairment (especially optic neuritis), seizure, subarachnoid hemorrhage, and cerebral infarction. Magnetic resonance imaging may show T2-weighted signals in subcortical matter suggestive of CNS vasculitis.[148]

Skin, GI, renal, and other systemic alterations have been well described in EGPA. Skin findings are present in 40% to 70% of cases and may develop in localized crops. They can manifest as nonthrombocytopenic purpura (particularly on the lower extremities), urticaria, a maculopapular rash, petechiae, ecchymoses, or livedo reticularis. Skin biopsies typically demonstrate eosinophilic infiltration and leukocytoclastic vasculitis.[168] Tender cutaneous or subcutaneous nodules (which may ulcerate) containing extravascular granulomas may preferentially involve the fingers, scalp, and extensor surface of the elbow.[148] GI manifestations of EGPA are present in up to 60% of cases. They can include eosinophilic gastroenteritis or vasculitis that can lead to diarrhea, abdominal pain, intestinal obstruction, cholecystitis, pancreatitis, bleeding, liver function test abnormalities, and bowel perforation.[148] GI disease also carries a poor prognosis and is the second leading cause of death in patients with EGPA.[148] A degree of renal insufficiency occurs in 25% to 50% of patients with EGPA. Eosinophilic interstitial nephritis with necrotizing features is the most common histopathologic finding, but focal segmental glomerulosclerosis, hematuria, and proteinuria also occur.[149,169,170] Severe, difficult-to-control hypertension is also a major sequela of EGPA. In contrast to granulomatosis with polyangiitis, overt renal failure is not commonly seen in EGPA.[149] Mild lymphadenopathy (in 30%–40%), rheumatologic manifestations (migratory polyarthralgias, myalgias, temporal arteritis), urologic disease (ureteral, urethral, prostatic), and ocular manifestations (scleritis, uveitis, optic neuropathy, conjunctival nodules) also have been described.[148]

Mechanisms of Disease

The pathogenesis of EGPA remains poorly understood. A possible pathogenic role of antineutrophil cytoplasmic antibody (ANCA) is suggested by the finding of ANCA in 40% to 60% of patients with EGPA.[150] ANCA may contribute to tissue inflammation and injury by activation of inflammatory cells, release of proteolytic enzymes, and generation of oxidative stress; alternatively, its presence may be a consequence rather than a cause of the tissue injury.[148] The strong association with allergy, atopy, eosinophilia, and elevated blood levels of type 2 cytokines and IgE (especially during the vasculitic phase of the disease) has raised the likelihood of augmented Th2 immunity.[148,171–174] Eosinophils likely also contribute significantly to the tissue injury since blood, BAL, and urine specimens contain eosinophil-derived cytotoxic granule proteins.[148,175] Based on these collective findings, it has been proposed that repeated antigenic stimulation in patients with a heightened T-cell and eosinophil response may be important in the development of the disorder. Heightened humoral immunity with immune complex disease also may play a role. Genetic factors including polymorphisms in the IL-10 gene, HLA-DQ, and HLA-DRB107 showed associations with EGPA[176] and support findings of heightened autoimmunity in EGPA.

Diagnostic Testing

Diagnosis rests on radiographic imaging, laboratory testing, examination of pathology, and application of diagnostic criteria.

Imaging Chest radiographs have transient, migratory, patchy, nonlobar, nonsegmental, often peripheral pulmonary infiltrates, with no regional predilection.[177–179] Nodular lesions, reticular opacities, bronchial wall thickening, bronchiectasis, and hilar adenopathy are less common. Cavitary lesions are less frequent than in GPA. Pleural effusions are common and may be associated with pleuritic chest pain.[179] The chest radiograph may occasionally be normal. HRCT scanning has demonstrated bronchial wall thickening, pulmonary artery enlargement (in comparison to the corresponding bronchi), irregular stellate configuration of some vessels, adenopathy, areas of interlobular septal thickening, and scattered patchy parenchymal opacities with ground-glass, nodular, consolidated, or tree-in bud appearance.[75] Nodules may be present within areas of ground glass.[92,179,180] These findings have been reported to correlate with pathologic findings evident on open lung biopsy such as eosinophilic pneumonia, alveolar hemorrhage, eosinophilic infiltration of the bronchial wall, and septum.[178]

Laboratory Testing Most patients with EGPA have a striking, but fluctuating, degree of peripheral blood eosinophilia (mean values between 5 and 20,000/mm^3; 20%–90% of the WBC differential) at diagnosis.[75,148] The degree of eosinophilia tends to parallel the vasculitis activity and may be suppressed by corticosteroid treatment of asthma. Serum C-reactive protein levels and total IgE levels are elevated (range, 500–1000 U/mL) in 75% of patients.[75] Elevated blood levels of type 2 cytokines IL-4, IL-5, and IL-13, as well as serum IgG4, TARC/CCL17, CCL26 (eotaxin-3), and urinary eosinophil–derived neurotoxin, also correlate with disease activity but are not currently used clinically. BAL fluid from patients with active EGPA also contains increased levels of the type 2 cytokines IL-4, IL-5, and IL-10 compared with inactive EGPA.[171,181–187] Rheumatoid factor titers may be positive, but antinuclear antibodies are usually negative.[148] Hypergammaglobulinemia and circulating immune complexes may also be seen.

Approximately 40% to 60% of patients with EGPA have positive antinuclear cytoplasmic antibodies with a perinuclear staining pattern (pANCA).[165,166,188] The majority of these are directed against myeloperoxidase (MPO) and a minority against proteinase 3 (PR3). The absence of ANCA does not exclude the diagnosis. Indeed, recent case series suggest that EGPA patients with positive and negative ANCA have different clinical features.[189] Patients with positive ANCA (the "vasculitic phenotype") tend to have biopsy-proven vasculitis, purpura, ENT manifestations, peripheral neuropathy, and renal disease, but have less cardiac involvement.[165,166,190] In contrast, those with negative ANCA (the "eosinophilic tissue infiltration phenotype") manifest more commonly with fever, eosinophilic pneumonia, and eosinophilic myocarditis.[165,166,191]

Laboratory examination of pleural fluid, if present, reveals an eosinophil-predominant exudate with low glucose levels.[148] Pleural biopsy shows chronic pleuritis with eosinophilic infiltration. BAL reveals an increased percentage of eosinophils, the magnitude of which is generally less than that seen with CEP or idiopathic HES. However, patients have been described whose BAL fluid leukocyte differential contained 81% eosinophils.[192]

Pathology Open lung biopsy is the gold standard for tissue biopsy but is rarely necessary. Transbronchial biopsy may reveal the diagnosis if there is alveolar involvement but is often nondiagnostic. In addition, the blood vessels required to make the diagnosis of vasculitis are often absent from transbronchial biopsies. Biopsy of other sites (e.g., skin, pericardium, muscle, nerve, gut), more often include a blood vessel and may be more helpful in establishing a diagnosis.

Although lung biopsy is rarely required for diagnosis, the histopathologic hallmarks of EGPA vary depending on the stage of illness but include tissue (interstitial, blood vessel, and alveolar) infiltration by eosinophils, eosinophilic necrotizing giant cell vasculitis of small arteries, arterioles, and, to a lesser extent, small veins, venules, and capillaries and perivascular and interstitial eosinophilic granulomas (typically microscopic).[193–195] Both pulmonary and systemic vessels may be affected. The precise histopathology of vascular impairment depends on the stage of the lesion. Early lesions demonstrate eosinophilic infiltration of the vessels and perivascular region (Fig. 71-4). Later lesions are characterized by necrotizing arteritis or vessel obliteration and scarring. The extent of vascular impairment varies from mild, eosinophilic perivascular cuffing to severe transmural inflammation with necrotization. Lesions may be sparse or widespread. In the lung the granulomas may have central necrosis with eosinophilic inflammation, may involve interlobular septae, and may extend along the pleura. Diffuse capillaritis and alveolar hemorrhage have been reported. Eosinophilic lymphadenopathy also may be present. Biopsies of skin, nerve, or muscle may also confirm the diagnosis.[162]

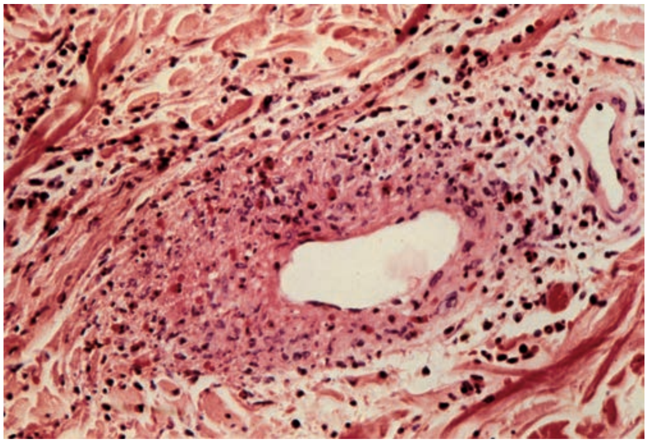

Figure 71-4 Pathologic appearance of small arteriole in eosinophilic granulomatosis and polyangiitis (EGPA). Intense perivascular inflammation with eosinophilia is present.

Diagnostic Criteria The diagnosis of EGPA is generally based on clinical features. Various diagnostic criteria have been reported.[152,195] In 1990, the American College of Rheumatology published diagnostic criteria for EGPA, based on assessments of the sensitivity and specificity of the diagnostic criteria used previously.[195] The presence of at least four of the following six criteria yielded 85% sensitivity and 99.7% specificity in establishing the diagnosis: (1) asthma, (2) peripheral eosinophilia greater than 10%, (3) mono- or polyarthropathy, (4) migratory or transient pulmonary infiltrates, (5) paranasal sinus abnormality, and (6) extravascular eosinophils in a blood vessel on a biopsy specimen. The presence of asthma or allergy as well as more than 10% eosinophilia was 95% sensitive and 99% specific in distinguishing EGPA among a subgroup of patients with well-documented systemic vasculitides. Subsequently, the Chapel Hill Consensus Conference recommended that diagnostic criteria for EGPA include (1) appropriate clinical setting and histopathology and (2) eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small and medium vessels with associated asthma and eosinophilia.[196] However, these criteria require tissue biopsy and are less sensitive for EGPA than others that have been proposed; hence, they may be less useful to assist diagnosis in the routine clinical setting.

The differential diagnosis of EGPA includes polyarteritis nodosa, microscopic polyangiitis, granulomatosis with polyangiitis, CEP, ABPA, idiopathic HES, Loeffler syndrome, asthma, fungal or parasitic infection, drug-induced vasculitis, sarcoidosis, and Hodgkin lymphoma. EGPA can be distinguished from granulomatosis with polyangiitis since compared with the latter, patients with EGPA have nasal polyps and allergic rhinitis but lack significant necrotizing upper airway lesions and cavitation of lung nodules and are more likely to have pANCA (in contrast to the cANCA seen in granulomatosis with polyangiitis). EGPA can be distinguished from MPO-positive microscopic angiitis since patients with the latter syndrome have leukocytoclastic vasculitis without granulomas and do not have upper airway involvement, asthma, and eosinophilia. Further, unlike EGPA, cardiac involvement is rare in microscopic polyangiitis. EGPA may be difficult to distinguish from idiopathic HES among patients who lack ANCA and/or neuropathy without overt vasculitis.[197] In this setting, EGPA is the more likely diagnosis in patients with lower eosinophil counts who later develop vasculitis.

Treatment and Prognosis

Patients in whom EGPA goes untreated have a poor prognosis: up to 50% die within 3 months after the onset of vasculitis. As such, efforts at early recognition and treatment are important.

The choice of treatment depends in part on the clinical features at the time of diagnosis, since the presence of some features portends a worse prognosis and requires a more aggressive treatment approach.[198–200] The 2011 revised five-factor score can aid in assessing prognosis. A point is assigned for each of the following features: age >65 years, cardiac insufficiency, renal insufficiency (serum creatinine ≥1.7 mg/dL), gastrointestinal involvement, and absence of ENT involvement.[190,200] A score ≥2 is associated with a poor prognosis.

In patients *without* poor prognostic features, corticosteroids are the mainstay of treatment and generally lead to dramatic clinical improvement, with disease stabilization or cure. Prednisone, 1 to 1.5 mg/kg/d (or 60 mg/d in adults) is given for 3 to 12 weeks, aiming to eliminate constitutional symptoms and cardiac, renal, neurologic, or other vasculitic manifestations. Higher doses (e.g., 15 mg/kg/d methylprednisolone) are occasionally required for control of life-threatening symptoms. Severe hypertension and mononeuritis multiplex often require prolonged steroid treatment and may be difficult to eliminate. Once the vasculitic phase is controlled, corticosteroids may be tapered, with doses titrated to maintain disease control. Low-dose prednisone (e.g., 5–10 mg) is often given every day or every other day for up to 1 year. Although relapses are uncommon, patients should be followed closely for evidence of clinical deterioration and should have periodic screening of total WBC and differential, ESR, and IgE levels. Most reports suggest the pANCA is not useful to monitor disease activity or direct therapeutic intervention, but one case series demonstrated that patients with ANCA-positive EGPA had more frequent relapses and lower 5-year relapse-free survival rates than ANCA-negative patients.[190]

Patients who have poor prognostic features at the time of disease presentation, or who have severe systemic involvement should receive high-dose intravenous methylprednisolone or oral prednisone for 3 days plus induction therapy with cyclophosphamide.[148,201,202] Patients treated with cyclophosphamide should be monitored closely for hemorrhagic cystitis, renal insufficiency, bone marrow suppression, bladder fibrosis, and urologic malignancies. Patients with severe disease treated with corticosteroids and cyclophosphamide have better survival than those treated with corticosteroids alone.[203] Azathioprine maintenance therapy (2 mg/kg/d) for 18 to 24 months may be beneficial once remission of disease has been achieved.[148,149,198] Methotrexate has been used along with glucocorticoids for induction and maintenance of therapy but is associated with a high relapse rate.[204]

Anti–IL-5 pathway agents are also effective in the treatment of EGPA. Compared to corticosteroids, they have fewer side-effects and require less frequent dosing. In a multicenter randomized control trial, the anti–IL-5 monoclonal antibody mepolizumab (300 mg every 4 weeks) led to more accrued weeks of remission, reduction in glucocorticoid dosing, and a lower relapse rate.[205] As a result, mepolizumab was FDA approved for use in EGPA.[206] The anti–IL-5 antibody reslizumab (3 mg/kg every 4 weeks) was associated with glucocorticoid reduction and improved symptoms in a cohort of 9 patients with EGPA.[207] In a series of five patients with EGPA the anti–IL-5 receptor α antibody benralizumab was associated with a reduction in glucocorticoid dose and improvement in patient reported outcomes.[208]

Intravenous immunoglobulin (IVIg) may be beneficial for use in pregnant women and for reducing symptoms and organ involvement and improving long-term disease control among persons with severe organ involvement in EGPA.[209] The immunoregulatory cytokine interferon α (IFN-α) has led to improved pulmonary function tests, reduction in corticosteroid dose, and decreased WBC count and may be considered as an alternative treatment in patients with refractory disease but may be of limited efficacy and can cause cardiac toxicity.[210] Plasma exchange may also be a successful adjunct treatment in some patients, particularly those with ANCA positivity and glomerulonephritis.[148,211] Rituximab may be effective as an alternate therapeutic agent, but further studies are needed to clarify benefits of treatment in EGPA as compared with other forms of ANCA-positive vasculitis.[212] Patients on prolonged courses of higher doses of glucocorticoids and other immunosuppressive agents should receive prophylaxis for *Pneumocystis jirovecii*.

Prolonged treatment may be necessary to maintain disease control. Long-term overall remission can be achieved in approximately 81% to 92% of patients; relapses occur in 25% of cases and are most common within 1 year.[148,162] In a series of 30 patients collected over the period 1950 to 1974, a median survival of more than 9 years was reported in patients treated with steroids; 1-year survival was 90%, 3-year survival was 76%, and 62% survival was noted at 5 years. More recent studies suggest 85% to 100% survival at 5 years.[75,190,202]

■ Hypereosinophilic Syndrome

Hypereosinophilic syndrome (HES) is a rare disorder first described in 1968 by Hardy and Anderson. In 1975, Chusid et al. revised the definition of HES to include only cases in which no other underlying cause of hypereosinophilia could be found.[213] HES is now recognized as a clinically heterogeneous syndrome with a wide range of disease severity. HES likely represents several diseases of distinct etiology that share common features.[214–216] Three appear to be most common.

The *myeloproliferative variant* (primary/neoplastic HES): In this variant there is clonal expansion of eosinophils related to stem cell, myeloid, or eosinophil neoplasms. Clinical features include anemia, thrombocytopenia, hepatosplenomegaly, elevated leukocyte alkaline phosphatase, circulating immature leukocytes, and elevated B_{12} levels.[217] The most common chromosomal abnormality noted is deletion on 4q12, leading to fusion of genes for and constitutive activation of the tyrosine kinase fusion protein FIP1L1-PDGFRA.[218] Other chromosomal abnormalities also have been reported.

The *lymphocytic variant* (secondary, reactive HES, ~30% of cases): This variant is related to clonal expansion of Th2 T cells with an abnormal surface antigen phenotype (CD3−/CD4+) and increased production of IL-5.[219,220] Increased amounts of IL-4, IL-13, GMCSF, and hypergammaglobulinemia may be present.[221] Skin and soft tissue involvement are the predominant clinical features of this variant.

The *idiopathic variant* (~50% of cases): The disturbances present in the previously noted variants are lacking, but end-organ damage is present.[216]

Clinical Presentation

HES is a rare disorder. Although persons of any age may be affected, disease onset is most common between 20 and 50 years of age.[222,223] Men are more frequently affected than women (9:1).[222] When it occurs in children, it often heralds a clonal hematologic disturbance.[223] There is no known racial or ethnic predisposition. Familial cases with autosomal dominant transmission have been reported.

Clinical features and symptoms vary according to the organ system(s) affected. Presenting complaints are often nonspecific and include weakness, fatigue, low-grade fevers, myalgias, cough, angioedema, rash, retinal lesions, and dyspnea. Involvement of virtually every organ system has been described. The respiratory system is affected in an estimated 63% of patients with HES.[224] The most common symptoms include a predominantly nocturnal cough, which is either nonproductive or productive of small quantities of sputum, wheezing, and dyspnea. In general, respiratory manifestations are mild.[224] Pulmonary hypertension, ARDS, and pleural effusions (which may be due to CHF) have been reported but are rare. In patients with pulmonary manifestations, the chest radiograph or CT may reveal transient focal consolidation, ground-glass opacities, or diffuse pulmonary infiltrates (with no predilection for any particular distribution), small nodules, pleural effusion(s), adenopathy, or pulmonary emboli.[213,224]

Cardiac disease is the major cause of morbidity and mortality in patients with HES.[222,225] The most common cardiac manifestations are progressive CHF due to eosinophilic myocarditis and endocarditis, intracardiac thrombi, and endocardial fibrosis.[222] Cardiac involvement in HES, which may be clinically silent, is believed to progress from an initial acute necrosis stage, followed by endocardial thrombus formation and eventually development of fibrosis, which may lead to restrictive cardiomyopathy or valvular dysfunction such as mitral regurgitation.[222] Intracardiac thrombus formation can lead to ischemic embolic events. The cardiac damage is believed to be mediated at least in part by eosinophil-derived granular protein (EDGP). Elevation in serum troponin can provide a clue to the presence of cardiac involvement in HES.[226] Cardiac involvement correlates poorly with the peripheral blood eosinophilia; hence echocardiographic follow-up at 6-month intervals is recommended. Cardiac MRI also detects eosinophil-mediated cardiac injury or intracardiac thrombus.[227]

Involvement of the central or peripheral nervous system, which occurs in up to 60% of patients, also is a major cause of morbidity.[228] Neurologic manifestations of HES include encephalopathy with neuropsychiatric dysfunction, memory loss, gait disturbances with or without signs of upper motor neuron injury, visual changes, and sequelae of thromboembolic events, including hemiparesis. Peripheral neuropathy with sensory and/or motor axonal loss (no vasculitic or eosinophilic infiltration) is extremely common in HES.

The bone marrow is universally affected in HES, and eosinophils make up to 25%–75% of the differential. Other hematologic manifestations are venous and arterial thromboembolism, anemia, thrombocytopenia, elevated vitamin B_{12} levels, hepatosplenomegaly, and lymphadenopathy (in 12%–20%).[229]

Cutaneous manifestations may include eczema, urticaria, angioedema, nodular or papular lesions, skin thickening, erythroderma, or dermatographia.[222,230] Mucosal ulcerations may develop. As noted, cutaneous manifestations are more likely seen among patients with the lymphocyte HES variant.[220] Patients with papules are likely to have the FIP1L1-PDGFRA variant.[231] GI (20%–30% of patients), renal (10%–20%), musculoskeletal, ocular, and endocrine manifestations also are all well described.

The organ damage in HES is believed to be due to both eosinophilic infiltration of tissues and tissue injury caused by thromboembolic events.[232,233] Eosinophils probably contribute to tissue damage via antibody-mediated cytotoxicity and the release of toxic granule products such as major basic protein and eosinophil cationic protein. The precise events inciting the extreme eosinophilia in HES are unknown, but several mechanisms have been proposed, including overproduction or abnormal activity of cytokines leading to eosinophilia, and defects in cytokine signaling or signal transduction.

Diagnostic Testing

Diagnostic methods in the evaluation of suspected HES are discussed below.

Laboratory Testing Findings associated with HES include peripheral blood eosinophilia $>1.5 \times 10^9$/L,[212] elevated total serum IgE (25%–38%), hypergammaglobulinemia, circulating immune complexes (32%–50%), and ESR above 15 mm/h (68%).[213] Anemia and elevated serum B_{12} and leukocyte alkaline phosphatase are present in the myeloproliferative variant.[234] Fungal and parasitic serologies, as well as analysis of body fluids for ova and parasites, are negative. Blood and BAL eosinophilia are both prominent in patients with pulmonary involvement.

Pathology Histopathologic examination of affected lung specimens most commonly reveals intense interstitial infiltration with eosinophils. Less commonly, necrotic areas of parenchyma are found. These are believed to be due to pulmonary microemboli. In contrast to EGPA, significant vasculitis is not present.

Diagnostic Criteria Current consensus defines hypereosinophilia as blood eosinophils $>1.5 \times 10^9$/L on two examinations separated by ≥1 month and/or tissue eosinophilia (defined as >20% of cells in a bone marrow specimen, tissue infiltration defined by a pathologist, and/or marked deposition of EDGP in tissue).[235] The term *HES* is defined as the presence of hypereosinophilia together with eosinophilic tissue infiltration and organ damage. Other causes of hypereosinophilia and organ damage should be excluded. Occasionally, the disease presents with the incidental finding of blood eosinophilia before development of other complications. The total peripheral leukocyte count is typically elevated to above 10,000 (typical range, 10,000 to 30,000), with a preponderance of eosinophils (up to 70%). The leukocytosis may be progressive. Tests recommended to assess for end-organ damage also include serum chemistries, liver function tests, CPK, troponin, ECG, echocardiogram, chest x-ray and/or CT, pulmonary function tests, abdominal CT scan, and tissue biopsy as indicated. Serum tryptase, vitamin $B_{12,}$ and Ig levels also may support the diagnosis.[236] In addition, patients with suspected HES should undergo bone marrow aspirate and biopsy, FIP1L1-PDGFRA mutation analysis, and T lymphocyte phenotyping by flow cytometry or karyotype analysis to evaluate for the HES subtypes noted earlier. Proper diagnosis of the HES subtypes has implications for choosing therapy for the disease.

The differential diagnosis of HES includes parasitic infection, acute eosinophilic leukemia, drug-induced hypersensitivity, EGPA, episodic angioedema with eosinophilia, tuberculous or fungal infection, allergic or autoimmune disease, other acute or CEPs, TPE, other lymphoproliferative disorders, and paraneoplastic syndromes (Table 71-5). Patients with eosinophilic leukemia have immature eosinophils or blasts in the bone marrow and/or blood, whereas patients with HES typically do not. Patients with HES do not have asthma or vasculitis characteristically associated with EGPA, and patients with episodic angioedema typically lack the multiorgan involvement associated with HES.

Treatment and Prognosis

Before the discovery of an effective therapy, the prognosis of HES was poor. In one early series, 81% of 48 patients died within 1 year of diagnosis. Overall, without therapy, average survival was 9 months, and 3- to 4-year survival was estimated at 10% to 12%.[213] The greatest mortality occurs within the first year after diagnosis. Death may occur from refractory CHF, azotemia, hepatic failure, venous thromboembolism, a perforated abdominal viscus, or infection. Patients with the myeloproliferative variant of HES (especially those with FIP1L1-PDGFRA-positive disease) tend to have an aggressive course with high mortality without treatment. The advent of effective therapy for HES has led to a marked improvement in median survival to more than 10 years.

Favorable prognostic features include a rapid clinical response to treatment with reduction in blood eosinophilia, the presence of angioedema, elevated IgE, and absence of findings associated with myeloproliferative disorder.[222,236–238] Factors associated with a poor prognosis in HES include presence of total blood WBC greater than 100,000/mm^3, myeloblasts in the peripheral blood, refractory CHF, basophilia above 3%, identifiable chromosomal abnormalities in bone marrow cells, and elevated serum B_{12}.[222,239]

Patients with the incidental finding of peripheral eosinophilia but without evidence of end-organ dysfunction can be followed closely at 3- to 6-month intervals without specific treatment, as they tend to follow a benign course. Patients should be monitored routinely at 6-month intervals with chemistries, ECG, echocardiogram, and pulmonary function tests as well as monitored for clinical signs of thrombotic complications. Additional monitoring and testing should be done as indicated depending on symptoms and other known organ involvement.

In patients presenting with life-threatening manifestations, including eosinophilia $>100 \times 10^9$/L, signs of cardiac or neurologic involvement, or thromboembolism, glucocorticoids should be initiated while awaiting the results of the initial evaluation. Those

TABLE 71-5 Comparative Features of the Pulmonary Eosinophilic Syndromes

	Loeffler	TPE	AEP	CEP	ABPA	EGPA	HES
Clinical course	Acute	Acute, subacute, chronic	Acute	Subacute	Acute, subacute, chronic	Acute, subacute, chronic	Subacute, chronic
Respiratory symptoms	Self-limited, mild	Severe	Severe	Mod-severe	Mod-severe	Mod-severe	Mild
Hx allergic disease/ asthma	—	—	±	+ (30%–60%)	Nearly 100%	100%	—
Blood eosinophilia	Mod to very high, but transient	Very high	May be absent (delayed)	Moderate in most	Typical	Very high, fluctuates	Extremely high, persistent
Sputum/BAL eosinophilia	+	+	++	++	±	+	++
Elevated serum IgE	Normal or elevated	High	Mod in some	Mod–high in 50%	Very high, fluctuates w/disease	Mod–high	Mod–high in some
Etiologic agent	*Ascaris, Ancylostoma*, *Necator, Strongyloides*, etc.	Filarial infection	Cigarette smoke, other inhaled exposures, unknown	Unknown	*Aspergillus* (or other fungus)	Unknown	Unknown
Radiographic findings (CXR, CT)	Patchy, often peripheral unilateral or bilateral consolidation and GGO; usually transient, migratory, nonsegmental	Diffuse, reticulonodular	Diffuse, alveolar and interstitial GGO and airspace opacities, interlobular septal thickening, pleural effusion	Predominantly, peripheral consolidation and GGO; "photographic negative of pulmonary edema"	Tram-track opacities, finger-in-glove opacities, fleeting opacities, bronchiectasis, and fibrosis	Transient, migratory peripheral, rarely diffuse; patchy peribronchial and septal thickening, patchy parenchymal GGO or consolidation, pleural effusion	Transient, focal or diffuse GGO or consolidation
PFTs	± Mild RVD	OVD early, RVD late, or mixed pattern	RVD	Normal, OVD, or RVD	OVD ± RVD	OVD ± RVD	Mild RVD in some
Characteristic diagnostic findings	Parasite larvae in sputum, BAL, gastric aspirate	Filaria-specific IgE, IgG, microfilaria in LN/lung	>25% eosinophils in BAL	None	See Table 71-4	Histopathology showing eosinophilic vasculitis plus appropriate clinical setting	Extreme, persistent eosinophilia and multiorgan dysfunction (no other cause)
Vasculitis	None	None	None	Occasionally mild, nonnecrotic	None	Characteristic (see text)	None
Extrapulmonary manifestations	GI late, if untreated	Cardiac, CNS rare	None	Very rarely reported	None	Typical of vasculitic phase	Cardiac, neurologic, GI, hematologic, other
Therapy	Mebendazole, if *Ascaris* or hookworm	Diethylcarbamazine	Stop exposure, corticosteroids	Corticosteroids	Corticosteroids, bronchodilators, antifungals, others (see text)	Corticosteroids, anti–IL-5 antibodies, other immunosuppressives (see text)	Depends on disease variant (see text)
Chronic/recurrent disease	None	Relapses may occur	None	Common	Typical	May occur (∼25%)	Chronicity typical

+, yes or present;—, no or not present; BAL, bronchoalveolar lavage; CT, computed tomography; GGO, ground-glass opacity; GI, gastrointestinal; Hx, history of; LN, lymph node; mod, moderately; OVD, obstructive ventilatory defect; CXR, chest x-ray (radiograph); PFTs, pulmonary function tests; RVD, restrictive ventilatory defect.

with possible exposure to *Strongyloides* should receive concomitant ivermectin. Doses ranging from 1 mg/kg/day of prednisone to 1 g of methylprednisolone may be used depending on the severity of illness.[239]

The tyrosine kinase inhibitor imatinib mesylate (initial dose 400 mg/d) is the first-line therapy for all patients with the PDGFRA-positive variant of HES.[215,218,240,241] Patients with cardiac involvement should receive concomitant systemic corticosteroid therapy to avoid further cardiac damage that might be induced by imatinib.[242] Case reports have suggested that other tyrosine kinase inhibitors, nilotinib and sorafenib, can be effective alternate therapies in cases of resistance to imatinib therapy.[243,244]

A mainstay of therapy for patients with HES and organ involvement who lack FIP1L1-PDGFRA fusion or other imatinib-responsive mutations includes glucocorticoids such as prednisone at 1 mg/kg/d for several weeks. If the disease stabilizes or resolves (e.g., if blood eosinophilia and symptoms are controlled), steroids can be tapered gradually to alternate-day dosing and should be continued for approximately 1 year at the minimal dose that effectively controls disease activity.[215]

Mepolizumab (300 mg every 4 weeks), an anti-IL-5 monoclonal antibody was associated with reduction in the number of flares of FIP1L1-PDGFRA-negative HES in a phase 3, multicenter, randomized, controlled trial.[100] An earlier study showed reduction in glucocorticoid dosing without increase in disease activity in FIP1L1-PDGFRA-negative HES patients receiving 750 mg of mepolizumab.[245] Mepolizumab (300 mg) is now approved by the FDA for treatment of HES ≥6 months of duration without an identifiable cause.[206] In a small phase 2 trial, benralizumab (30 mg every 4 weeks), an anti–IL-5 receptor α monoclonal antibody, was associated with a reduction in absolute eosinophil count in PDGFRA-negative HES.[246]

IFN-α and hydroxyurea were used more often prior to the approval of IL-5 pathway biologics, and are less likely to be needed, at least as monotherapy, in patients who can receive those agents. IFN-α, a mediator that suppresses eosinophil function in vitro, has been beneficial in management of HES, perhaps by inhibiting eosinophil proliferation and differentiation. IFN-α can be tried as a second-line agent in patients with HES or as a steroid-sparing agent.[215] IFN-α monotherapy should be avoided among patients with lymphocyte-variant disease.[247] Pegylated interferon may be an effective alternate therapy in selected cases.[248] Hydroxyurea (0.5–1.5 g per day) may be added to the regimen if there is evidence of further disease progression or steroid toxicity, with the aim of reducing the peripheral leukocyte count to the range of 5000 to 10,000.[215]

Vincristine may be used as a chemotherapeutic inducing agent in patients with extremely high peripheral WBC counts.[216] The JAK inhibitors tofacitinib and ruxolitinib have been used successfully in a small case series of lymphoid or idiopathic HES with cutaneous involvement.[249] Case reports have also demonstrated efficacy of the anti–CD-52 antibody alemtuzumab, which targets eosinophils and T cells in the lymphocyte variant of HES.[250–252]

Allogeneic bone marrow transplantation has also been reported anecdotally to be successful in selected severe cases of HES in which end-organ damage is potentially reversible.[253] Anticoagulation with warfarin and/or antiplatelet agents may be needed for management of thromboembolic events.[225]

DRUG- AND TOXIN-INDUCED EOSINOPHILIC PNEUMONIA

A vast number of drugs and toxic exposures have been associated with the development of pulmonary eosinophilia, most commonly leading to eosinophilic pneumonia, making this a very common cause of eosinophilic pneumonia.[54,254–257] Drug- and toxin-induced eosinophilic lung disease is a heterogeneous syndrome and may be classified as acute eosinophilic pneumonia or chronic eosinophilic pneumonia. When associated with rash, fever, and other systemic symptoms it is called *drug reaction with eosinophilia and systemic symptoms (DRESS)*. A partial list of drugs that have been associated with eosinophilic pneumonia is given in Table 71-6, and information regarding pulmonary drug toxicities may also be found online at *www.pneumotox.com*. Of the medications implicated, many are commonly used antibiotics, nonsteroidal anti-inflammatory agents, anticonvulsants, cardiovascular medications, and antidepressants. In addition to medications, a number of toxic exposures also may be associated with eosinophilic pneumonia.[257] For example, eosinophilic pneumonia has been described following radiation therapy for breast and lung cancer,[257–259] after exposure to iodinated contrast agents or 1,1,1-trichloroethane (Scotchgard),[260] and after inhalation of cocaine or heroin.[59,261] Nicotine- and vaping-induced AEP have been described above.

TABLE 71-6 Drugs That Cause Eosinophilic Pneumonia

Drug Class	Specific Drug
Angiotensin-converting enzyme inhibitor	Captopril, perindopril
Antidepressant	Fluoxetine, imipramine, venlafaxine
Antiepileptic	Carbamazepine, levetiracetam, phenytoin, valproic acid
Antimicrobial	Azithromycin, chloroquine, dapsone, daptomycin, ethambutol, minocycline, nitrofurantoin, penicillins, pyrimethamine, sulfonamides
Anti-inflammatory	Acetaminophen, gold salts, infliximab, montelukast, mesalamine, methotrexate, NSAIDs (acetylsalicylic acid, ibuprofen, indomethacin, naproxen), tacrolimus, zafirlukast
Chemotherapeutic	Bleomycin, fludarabine, gemcitabine
Other	Amiodarone, cannabinoids, cocaine, heroin, iodine contrast, L-tryptophan, propylthiouracil, simvastatin, tobacco smoke

Data collected from pneumotox.com[256] and references 254, 255, and 257.

Whereas most cases of drug- or toxin-induced pulmonary eosinophilia are sporadic, outbreaks of pulmonary eosinophilia have occurred following ingestion of rapeseed oil (contaminated with aniline derivatives)[262] or L-tryptophan.[263] The precise incidence of drug- or toxin-induced pulmonary eosinophilia is difficult to assess, since most of the literature pertaining to these syndromes is published in the form of case reports, rather than large series or controlled trials. For the same reason, the precise pathogenesis and the definition of the clinical syndromes associated with individual exposures are difficult to characterize.

■ Clinical Features

A diagnosis of drug- or toxin-induced eosinophilic pneumonia is based upon a careful history and review of medications and other drugs and exposures (including nonprescription drugs, herbal preparations, street drugs, and environmental exposures). Other causes of eosinophilic lung disease must be excluded. A concurrent skin rash and pleural effusion can support the diagnosis of drug-induced eosinophilic pneumonia.

In general, drug-induced pulmonary eosinophilic syndromes have an acute or subacute onset and are not always related to either

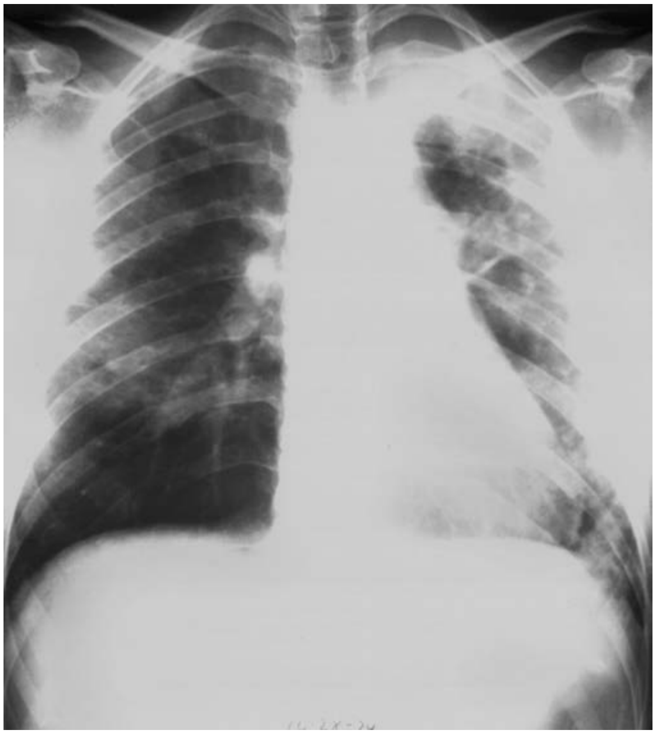

Figure 71-5 Chest radiograph of a 23-year-old woman with acute sulfasalazine-induced eosinophilic pneumonia. Bilateral interstitial and alveolar infiltrates are present.

the cumulative dose of the drug or the duration of treatment. Respiratory symptoms vary widely in severity, from a mild illness with dyspnea, cough, wheezing, and fever to severe fulminant respiratory failure. The DRESS syndrome consists of acute eosinophilic pneumonia with drug rash and systemic manifestations.[264]

■ Diagnostic Testing

In general, laboratory testing does not help to establish the diagnosis. Peripheral blood eosinophilia may be present but does not exclude the diagnosis of drug- or toxin-induced eosinophilic pneumonia.[255] The most common radiographic findings were bilateral airspace consolidations and ground-glass opacities in an asymmetric and peripheral distribution (Fig. 71-5). In half of the cases, the infiltrates involved mainly the upper lobes.[265] Multiple, small nodules in a centrilobular distribution and interlobular septal thickening also were observed.[265]

■ Diagnostic Criteria

Diagnostic criteria include the following: (1) acute or chronic eosinophilic pneumonia by diagnostic criteria (eosinophilia on lung biopsy or in BAL fluid (typically >25%) in the setting of parenchymal infiltrates; (2) a potential candidate drug or toxin in an appropriate time frame; (3) exclusion of other causes of eosinophilic pneumonia, such as infection; (4) clinical improvement after cessation of the drug or toxin; and (5) recurrence with re-challenge to the drug or toxin. (Although, in practice, clinical improvement after cessation of a suspected agent is usually sufficient to complete the diagnosis without the need for re-challenge.)

■ Treatment and Prognosis

The prognosis is favorable in most cases. Elimination of exposure to the drug or other toxin usually leads to resolution of symptoms, eosinophilia, pulmonary infiltrates, and normalization of lung function within a month. Supplemental therapy with corticosteroids is not universally required, but it may hasten recovery in patients who are severely ill.[255]

CHAPTER 72

Pulmonary Arterial Hypertension

Nick H. Kim
Jess Mandel
Kimberly A. Smith
Jason X.-J. Yuan

INTRODUCTION

Pulmonary arterial hypertension (PAH) is a progressive disease of the pulmonary vasculature that results in right heart failure and excess morbidity and mortality without effective treatment. Although rapid progress has resulted in the availability of therapies that can improve the outlook for many patients, true full reversal of disease remains elusive. Furthermore, long delays in disease recognition are common, exposing patients to prolonged suffering and potentially irreversible harm. PAH should not be confused with other mechanisms leading to elevation of pulmonary arterial pressure, such as hypoxemic lung disorders (e.g., chronic obstructive pulmonary disease [COPD], interstitial lung disease [ILD]), left heart disease (e.g., systolic, diastolic, or valvular dysfunctions), or chronic thromboembolism.[1,2] Prompt and accurate diagnosis of PAH followed by treatment based on the latest evidence-based guidelines are essential in successfully managing PAH.

CLASSIFICATION OF THE PULMONARY HYPERTENSIVE DISEASES

A "sclerosis of the pulmonary arteries" ("Uber Sklerose der Lungen Arterie") without identifiable cause was first described by Ernst von Romberg in 1891.[3] Exclusively descriptive reports of pathologic findings continued until the 1950s when the development of catheterization techniques allowed for hemodynamic evaluation. Using such methods, Dresdale et al. described a hypertensive vasculopathy of the pulmonary circulation involving vasoconstriction, elevation of pulmonary arterial pressure (PAP), and a measurable response to the injection of the nonselective α-adrenergic antagonist tolazoline.[4] No cause could be identified for the pulmonary arteriopathy, and the term *primary pulmonary hypertension (PPH)* was introduced.[5]

Subsequent classification schemes for diseases causing pulmonary hypertension have been adopted by international consensus panels. These have evolved from systems based primarily on histopathologic findings to a current model that emphasizes the grouping of entities according to similarities in etiology and clinical characteristics (Table 72-1).[6]

TABLE 72-1 Updated Classification of Pulmonary Hypertension[a]

1.	Pulmonary arterial hypertension	
	1.1	Idiopathic PAH
	1.2	Heritable PAH
	1.3	Drug and toxin induced
	1.4	Associated with:
	1.4.1	Connective tissue disease
	1.4.2	HIV infection
	1.4.3	Portal hypertension
	1.4.4	Congenital heart diseases
	1.4.5	Schistosomiasis
	1.5	PAH long-term responders to calcium channel blockers
	1.6	PAH with overt features of venous/capillaries (PVOD/PCH) involvement
	1.7	Persistent PH of the newborn syndrome
2.	Pulmonary hypertension due to left heart disease	
	2.1	PH due to heart failure with preserved LVEF
	2.2	PH due to heart failure with reduced LVEF
	2.3	Valvular heart disease
	2.4	Congenital/acquired cardiovascular conditions leading to postcapillary PH
3.	Pulmonary hypertension due to lung diseases and/or hypoxia	
	3.1	Obstructive pulmonary disease
	3.2	Restrictive lung disease
	3.3	Other pulmonary diseases with mixed restrictive and obstructive pattern
	3.4	Hypoxia without lung disease
	3.5	Developmental lung disorders
4.	PH due to pulmonary artery obstructions	
	4.1	Chronic thromboembolic PH
	4.2	Other pulmonary artery obstructions
	4.2.1	Sarcoma (high or intermediate grade) or angiosarcoma
	4.2.2	Other malignant tumors (e.g., renal carcinoma, uterine carcinoma, germ cell tumors of the testis)
	4.2.3	Non-malignant tumors (e.g., uterine leiomyoma)
	4.2.4	Arteritis without connective tissue disease
	4.2.5	Congenital pulmonary artery stenoses
	4.2.6	Parasites (e.g., hydatidosis)
5.	PH with unclear and/or multifactorial mechanisms	
	5.1	Hematologic disorders (e.g., chronic hemolytic anemia, myeloproliferative disorders)
	5.2	Systemic and metabolic disorders (e.g., sarcoidosis, pulmonary Langerhans cell histiocytosis, Gaucher disease, glycogen storage diseases, neurofibromatosis)
	5.3	Others (e.g., chronic renal failure with or without hemodialysis, fibrosing mediastinitis)
	5.4	Complex congenital heart disease

It is important to note the specific nomenclature purposefully adopted in the current classification scheme. The group of patients with PAH is identified as distinct from those patients with other causes of pulmonary hypertension (e.g., due to chronic left heart or respiratory disease). This grouping recognizes similarities in the histologic and many clinical features of patients with identifiable genetic causes of PAH (i.e., those with heritable PAH), those with collagen vascular or other diseases known to be associated with PAH (associated PAH), and patients in whom no known associated entity or genetic cause has been found. This last group is referred to as having *idiopathic PAH (IPAH)*. IPAH replaces the previously (and often loosely) applied term "PPH." Abandonment of the term "primary" also is important as a means of discouraging the use of the confusing and clinically inappropriate term "secondary" pulmonary hypertension. Use of such "primary" and "secondary" groupings may inappropriately suggest clinical similarities among the many very different conditions previously referred to as "secondary" pulmonary hypertension (e.g., patients with COPD and those with congenital heart disease). It may also promote a failure to recognize important similarities in clinical features (including appropriate treatment) between what was previously called "primary" pulmonary hypertension and entities inappropriately labelled "secondary" (e.g., patients with Eisenmenger syndrome or HIV infection).

DETERMINANTS OF PULMONARY ARTERY PRESSURE AND PULMONARY VASCULAR RESISTANCE

The pulmonary circulation normally is a high-flow, low-resistance, low-pressure system that carries blood into the pulmonary microcirculation where the blood takes up oxygen and unloads excess carbon dioxide. PAP is the product of cardiac output (CO) and pulmonary vascular resistance (PVR) as shown in Equation 1 (Eq. 1), where PVR is the vascular resistance of the entire lung, including the pulmonary arteries, capillaries, and veins.

$$\mathrm{PAP} = \mathrm{CO} \times [\mathrm{PVR}_{\text{arteries}} + \mathrm{PVR}_{\text{capillaries}} + \mathrm{PVR}_{\text{veins}}] \qquad \text{(Eq. 1)}$$

From this equation, it is clear that PAP can be raised by an increase in CO or an increase in arterial, capillary, or venous resistance. It would be expected then, that during periods of increased CO, such as during strenuous exercise, there would be a significant increase in PAP. However, in a normal healthy individual, the PAP is only slightly increased during periods of increased CO due to the compensatory increase in the cross-sectional area of the pulmonary vascular bed (due to recruitment of previously unperfused vessels and distension of vessels) resulting in a decreased PVR.[7] Arterial distension and optimal recruitment are dependent upon the compliance of the blood vessel walls. Loss of this compliance and recruitability due to vascular remodeling leads to pulmonary hypertension. As demonstrated in Eq. 1, an increase in PVR of any of the three components of the pulmonary vasculature can lead to an increase in PAP.[8]

Eq. 1 demonstrates the physical laws that govern blood flow in the lungs. To further understand and use this equation, it is important to understand its physical and anatomic foundations. When a liquid (e.g., blood) flows through a cylindrical tubular structure (e.g., a blood vessel), the resistance (e.g., PVR) is inversely proportional to the fourth power of the radius of the lumen of the tube. This is demonstrated by the Poiseuille equation (Eq. 2), where L is the length of the tube (or vessel), r is the inner radius of the tube, and η is the coefficient of viscosity of the liquid (blood). Therefore, even small changes in the radius of a vessel can significantly change the PVR.[8]

$$\mathrm{PVR} = (8L\eta)/(\pi r^4) \qquad \text{(Eq. 2)}$$

PULMONARY VASCULAR STRUCTURAL AND FUNCTIONAL CHANGES IN PULMONARY HYPERTENSION

Regardless of the initial genetic or pathogenic trigger, the increased PVR seen in pulmonary hypertension can be attributed to the collective effects of sustained vasoconstriction, vascular remodeling, in situ thrombosis, and increased arterial wall stiffness (Fig. 72-1).[8–13]

PAH and pregnancy: physiological changes, challenges, and outcomes. Adv Pulm Hypertens. 2011;10(3).)*

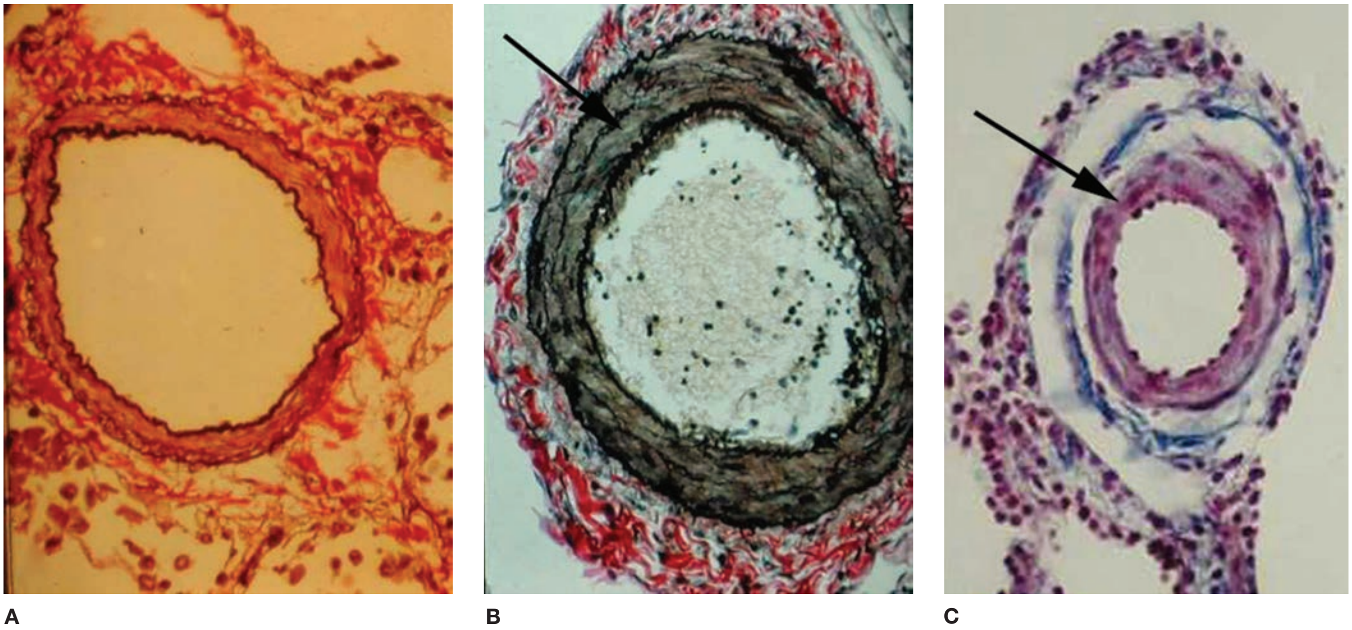

Figure 72-2 Vascular remodeling. As compared with a normal vessel (**A**), hypertrophy of smooth muscle cells *(arrow)* is seen in the pulmonary artery of a patient with pulmonary arterial hypertension (**B**). Extension of muscle *(arrow)* into normally nonmuscularized small intra-acinar pulmonary vessels is another prominent feature of pulmonary arterial hypertension (**C**). *(Reproduced with permission from Taichman DB: Pulmonary Vascular Disease. Philadelphia, PA: WB. Saunders; 2006.)*

A rise in cytosolic free Ca^{2+} concentration ($[Ca^{2+}]_{cyt}$) in pulmonary arterial smooth muscle cells is a major trigger for vasoconstriction and a key stimulus for pulmonary arterial smooth muscle cell proliferation and migration, which contributes to pathologic vascular remodeling.

Sustained Vasoconstriction

Pulmonary vasoconstriction can be a major contributor to increased PVR and hence PAP. Vasoconstrictive lesions include medial hypertrophy involving an increase in the number and size of pulmonary arterial smooth muscle cells. The elevated PAP and sustained vasoconstriction in PAH can, in turn, enhance pulmonary arterial smooth muscle cell hypertrophy and hyperplasia.[14] Marked smooth muscle hypertrophy can eventually cause medial atrophy, fibrosis, and the subsequent thinning of the media and dilation of the vessel lumen. Extension of pulmonary arterial smooth muscle cells into vessels normally only partially muscularized or nonmuscularized is a common and often prominent feature of precapillary vessels (Fig. 72-2).[15]

Hypoxic pulmonary vasoconstriction is an adaptive mechanism important for redirecting blood flow away from poorly ventilated areas of the lung and into the better ventilated areas to optimize ventilation–perfusion matching and maximize oxygenation of blood.[16–19] Hypoxia induces vasoconstriction in pulmonary arteries isolated without the endothelium and also induces contraction in a single isolated pulmonary arterial smooth muscle cell model, indicating that hypoxic pulmonary vasoconstriction is an intrinsic property of pulmonary arterial smooth muscle cells. In chronic hypoxia, two factors contribute to increased PAP: vascular remodeling due to pulmonary arterial smooth muscle cell proliferation and sustained vasoconstriction and structural changes that develop within a matter of weeks.[20,21] This remodeling is characterized by thickening of the media of the small pulmonary arteries and arterioles, and by peripheral extension of muscle into minute pulmonary vessels that are normally devoid of muscle (Fig. 72-2).[22] Although the precise mechanism by which hypoxia induces pulmonary vasoconstriction is still somewhat unclear, the signaling pathways initiated in response to acute and chronic hypoxia seem to relate, at least in part, to disrupted Ca^{2+} homeostasis.[8,23]

Vascular Remodeling

The thickness and tissue mass of the pulmonary arterial walls are maintained at an appropriate level by a fine balance between proliferation and apoptosis of fibroblasts, pulmonary arterial smooth muscle cells, and pulmonary arterial endothelial cells. Thickening of the vessel wall and luminal narrowing and eventual obliteration can occur if the balance is tipped in favor of cellular proliferation. These structural changes that lead to and include hypertrophy and/or luminal occlusion are referred to as pulmonary vascular remodeling.[24–26] The precise cellular and molecular mechanisms contributing to vascular remodeling are extremely complex. However, vasoconstriction and cellular proliferation share a common pathway. Increased proliferation and hypertrophy of pulmonary arterial smooth muscle cells have been implicated in the development of PAH, and these processes, like vasoconstriction, relate in part to disturbed Ca^{2+} homeostasis.[7] Resting $[Ca^{2+}]_{cyt}$ is increased in proliferating pulmonary artery smooth muscle cells compared with growth-arrested cells, demonstrating a role for enhanced Ca^{2+} in both proliferation and vasoconstriction.[27,28] In addition to increased proliferation, decreased apoptosis has been implicated in the development and maintenance of severe pulmonary hypertension,[29] and induction of apoptosis has been shown to promote the regression of hypertrophied pulmonary vascular walls in animal experiments.[30] Hypoxia can induce proliferation of pulmonary arterial adventitial fibroblasts, and in pulmonary hypertension patients, hypoxia induces the appearance of α-smooth muscle actin in the proliferative and matrix-producing fibroblasts, suggesting these cells have transdifferentiated into myofibroblasts.[31] Therefore, fibroblasts may play an important role in vascular remodeling due to hypoxia.

Complex lesions such as plexiform lesions also contribute to vascular remodeling. Plexiform lesions are aneurysmatic dilations of a muscular artery that can occur in very small arteries and arterioles.[8,32] These lesions are often found in patients with IPAH, but they also occur in the lungs of patients with severe PAH associated with left-to-right cardiac shunts, HIV infection, liver cirrhosis, and scleroderma. Although not pathognomonic, the plexiform lesion has been the focus of many studies of the cellular and molecular pathogenesis of PAH.[33–36] They contain collections of proliferating endothelial and smooth muscle cells, together with myofibroblasts and matrix proteins that can partially or completely occlude the vessel lumen. Narrowing or complete obliteration of the parent vessel by intimal thickening is a frequent associated finding, as is destruction of its media. Plexiform lesions often coexist with other obliterative vascular changes such as concentric laminar intimal thickening.[37]

The origin of plexiform lesions is complex and somewhat controversial. Originally, plexiform lesions were considered a congenital malformation.[38] Currently, there are investigators who believe that plexiform lesions develop due to the proliferation of pulmonary arterial smooth muscle cells that transform into myofibroblasts.[39–41] Other investigators propose that, in IPAH patients, plexiform lesions develop due to an endothelial-initiated response to cytokines, growth factors, or vascular injury.[39,41,42] Endothelial cells isolated from the plexiform lesions of IPAH patients proliferate in a monoclonal fashion. However, plexiform lesions from patients with forms of pulmonary hypertension other than IPAH develop from a polyclonal cell population, suggesting that different mechanisms contribute to plexiform lesion development in different forms of PAH.[8,43]

In Situ Thrombosis

Monoclonal proliferation of pulmonary arterial endothelial cells, pulmonary arterial smooth muscle cell migration, and accumulation of circulating inflammatory cells, platelets, and progenitor cells can result in occlusion of smaller vessels.[11,42] Thrombosis is frequently seen within the small vessels of patients with PAH. This occurs without evidence of a remote (embolic) source of the thrombus,[44–47] suggesting a local imbalance of pro- and anticoagulant forces. Activation and altered function of the endothelium leading to a shift from anti- to procoagulant activities might be due to the effects of shear stress associated with elevated pressure and/or flow. In addition to altered endothelial cell activity, platelets also promote thrombus formation by releasing vasoactive and mitogenic factors such as thromboxane metabolites and serotonin.[48] These, as well as other platelet-derived products (e.g., platelet-derived growth factor [PDGF], transforming growth factor-beta [TGFβ], and vascular endothelial growth factor [VEGF]) likely also contribute to the remodeling of vessel walls seen in PAH.

Increased Arterial Wall Stiffness

Increased arterial wall stiffness can also contribute to increased PVR.[49,50] The normal turnover of extracellular matrix proteins is accelerated with remodeling of the vasculature in PAH patients.[51,52] The expression of tenascin-C, as an example, is increased in experimental pulmonary hypertension induced by either monocrotaline in rats or increased blood flow in swine.[53–55] Indeed, inhibition of tenascin-C expression by antisense RNA ameliorates monocrotaline-induced pulmonary vascular lesions.[56] Elevated levels of this extracellular matrix protein are also seen on pulmonary arteries of patients with PAH.[57,58] Decreased vascular compliance resulting in the inability to recruit previously unperfused vessels due to increased parenchymal stiffness can also contribute to the development of PAH.[11,42] As a result, there is little capacity for distention and modest increases in pulmonary blood flow can elicit disproportionate elevations in PAPs. This situation is in marked contrast to that of the normal pulmonary circulation, in which an amputation of considerable lung parenchyma rarely suffices, per se, to raise PAPs to pulmonary hypertensive levels, as the remaining vessels retain their normal high capacitance. In some interstitial lung diseases, such as progressive systemic sclerosis, the parenchymal disease and the pulmonary vascular disease can evolve independently. In other connective tissue disorders, such as systemic lupus erythematosis, combinations of interstitial disease and intrinsic vascular abnormalities can contribute to pulmonary hypertension. While there are many structural changes in the pulmonary vasculature that lead to the development of PAH, vasoconstriction and vascular remodeling characterized by intimal, medial, and adventitial hypertrophy are the major structural changes that contribute to the increased PVR/PAP seen in PAH patients.

No single histologic feature distinguishes between the clinical PAH diagnoses. Each of the changes described can be seen in varying proportions in all clinical forms of PAH. For example, the vascular remodeling seen in chronic hypoxia-induced pulmonary hypertension is virtually indistinguishable from that seen in IPAH.[8] The predominant causes of the increased PVR in patients with PAH are sustained vasoconstriction, vascular remodeling, in situ thrombosis, and increased arterial wall stiffness. Persistent pulmonary hypertension, regardless of the cause, can ultimately lead to the development of cor pulmonale with hypertrophy of the right ventricle, its eventual dilation, and ultimately its failure (Fig. 72-3).

PATHOGENIC MECHANISMS OF PULMONARY HYPERTENSION

The pathogenic mechanisms leading to pulmonary hypertension have been conceptualized in six categories (Table 72-2): (1) *passive,* due to obstruction to pulmonary venous outflow (e.g., fibrosing mediastinitis, mitral stenosis, or left heart failure); (2) *hyperkinetic,* due to abnormally high pulmonary blood flow (e.g., left-to-right shunts); (3) *obstructive,* due to pulmonary thromboembolic disease; (4) *obliterative,* due to destruction of the pulmonary vascular bed by parenchymal proliferative disease; (5) *vasoconstrictive,* due to hypoxic vasoconstriction; and (6) *idiopathic* (i.e., without discernible cause).[59] Each mechanism leads to pulmonary vascular remodeling discussed previously, although the progression and reversibility may vary between entities. Other anatomic alterations can be seen in several categories, and, over time, distinctions between categories tend to become blurred (e.g., thrombosis may complicate obliterative vascular disease). Also, by the time pulmonary hypertension becomes manifest clinically, the pulmonary arterial tree has undergone considerable remodeling that limits its area and distensibility.

These mechanisms share commonality with the clinical classification of pulmonary hypertension, although overlap of mechanisms occurs. The most clearly linked is chronic thromboembolic pulmonary hypertension (CTEPH) with the obstructive mechanism. The most common form of pulmonary hypertension, that related to left heart disease, can also closely be tied to its passive mechanism along with fibrosing mediastinitis, which is classified in group 5 with unclear multifactorial mechanisms. Pulmonary hypertension due to lung diseases and/or hypoxia, group 3, can be understood as having two primary pathogenic mechanisms, vasoconstrictive in the chronic hypoxic subset and obliterative in the parenchymal disease/fibrosis subset, although these two often overlap. Group 5, pulmonary hypertension with unclear multifactorial mechanisms, contains multiple pathogenic mechanisms. Group 1 remains the most diverse and difficult to equate to a particular mechanism, as hyperkinetic, vasoconstrictive, obliterative, and other idiopathic mechanisms may all contribute to disease pathophysiology.

GENETIC, CELLULAR, AND MOLECULAR MECHANISMS OF PULMONARY ARTERIAL HYPERTENSION

The development of PAH involves increased PVR due to sustained vasoconstriction, vascular remodeling, in situ thrombosis, and

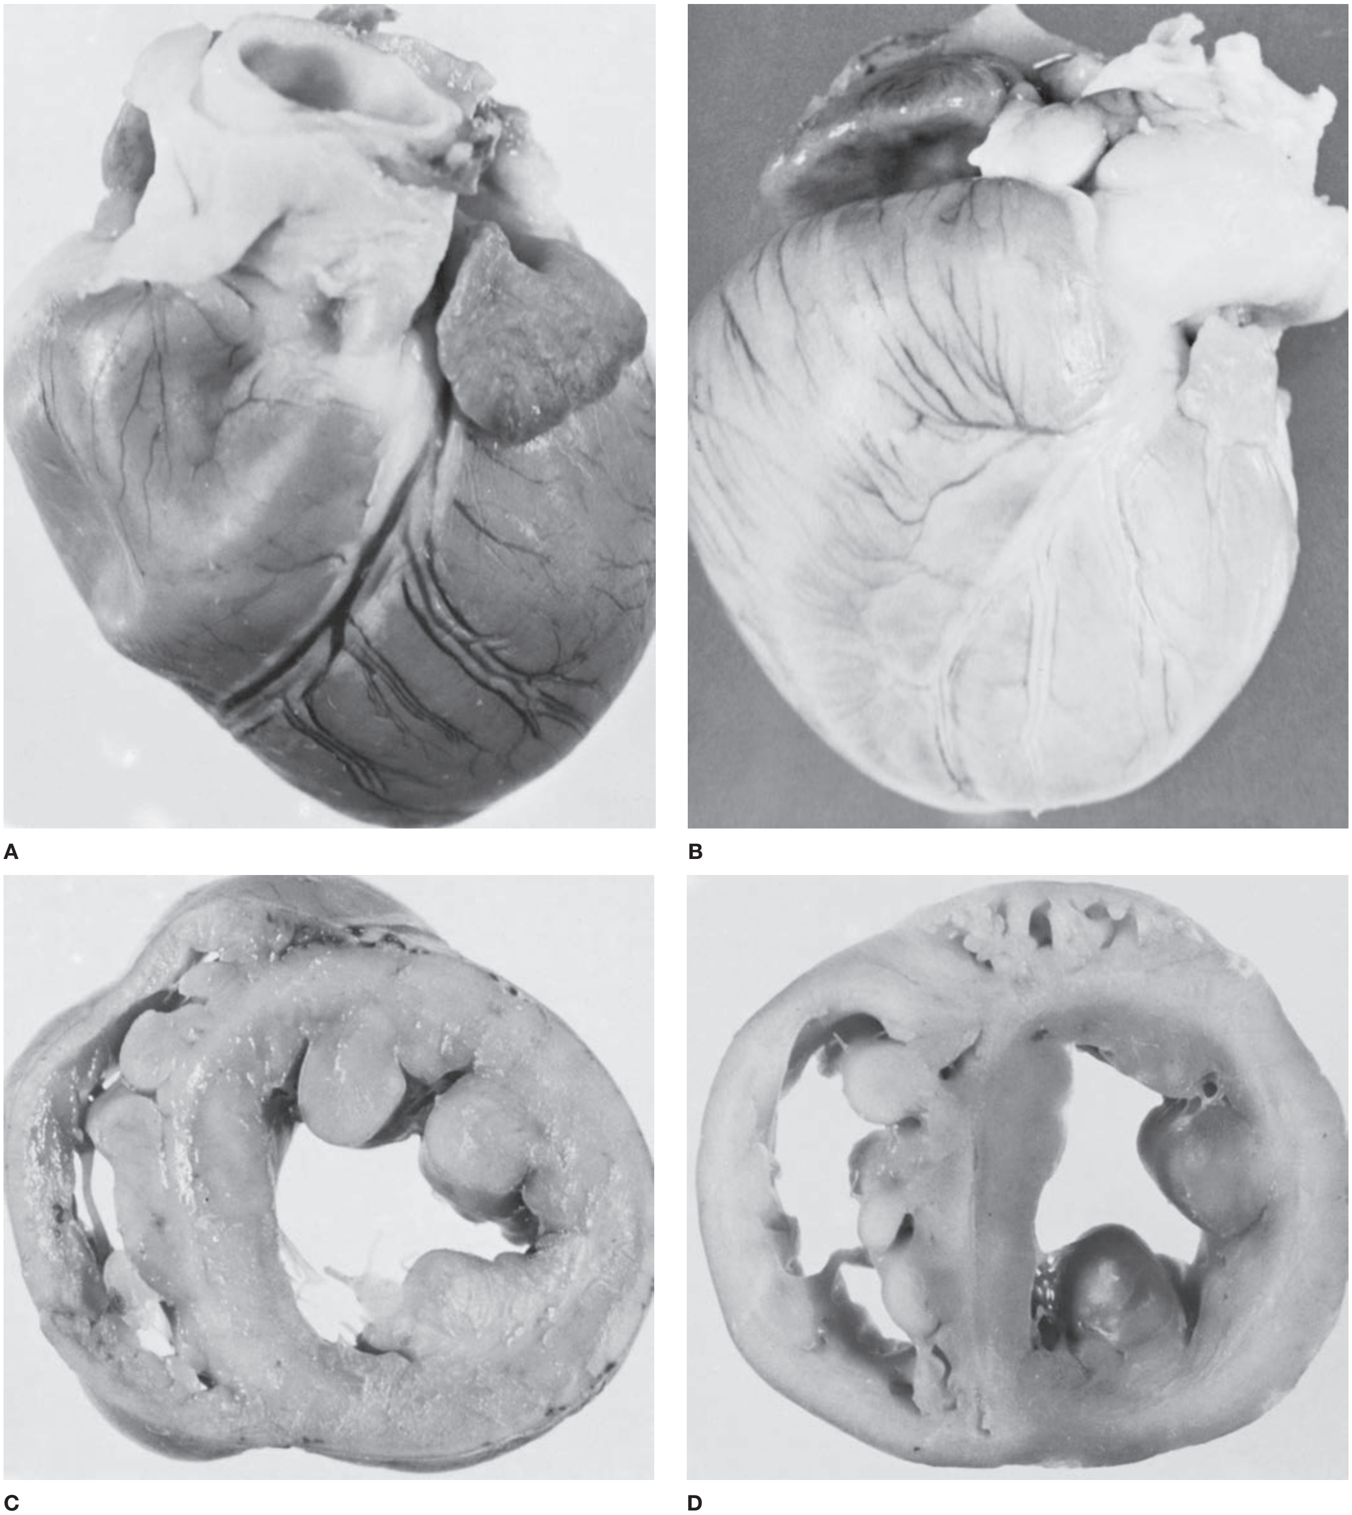

Figure 72-3 Right ventricular hypertrophy and dilatation in experimental pulmonary arterial hypertension in the dog. **A.** Normal heart. **B.** Changes from severe pulmonary hypertension. **C.** Cross section of normal heart to show thin wall of the right ventricular cavity. **D.** Cross section of heart with pulmonary hypertension show hypertrophy of the right ventricular myocardium and enlargement of the right ventricular cavity. *(Reproduced with permission from Dr. B. Atkinson.)*

increased atrial wall stiffness (Fig. 72-1). Abnormalities in the expression of numerous vasoactive mediators, vasoconstriction mediators, growth factors, and cytokines cause or result from changes in pulmonary arterial endothelial cells, pulmonary arterial smooth muscle cells, and platelet function and together result in a thickened vessel wall and markedly narrowed or even completely obliterated lumen. Some of the mechanisms for this combination of uncontrolled vasoconstriction, cell proliferation, and thrombosis are highlighted here.

■ Imbalance of Vasoactive Mediators

Relative deficiencies of factors with vasodilatory properties and a simultaneous excess in those promoting vasoconstriction have been noted in both animal models and patients with PAH. In addition

TABLE 72-2 Pathogenetic Mechanisms of Pulmonary Hypertension

	Mechanism	Examples
Passive	Pulmonary venous hypertension	Mitral stenosis, left atrial myxoma, fibrosing mediastinitis, pulmonary venoocclusive disease
Hyperkinetic	Increased pulmonary blood flow[a]	Left-to-right intracardiac shunts
Obstructive	Thromboembolic pulmonary vascular disease	High grade obstruction of large pulmonary arteries by organized thromboemboli, multiple pulmonary emboli
Obliterative	Inflammatory and/or proliferative pulmonary vascular disease	Interstitial lung disease, pulmonary arterial hypertension, schistosomiasis
Venoconstrictive	Hypoxia	High altitude, chronic bronchitis and emphysema (COPD)
Idiopathic	Unknown	Drug-associated pulmonary hypertension, portopulmonary hypertension, HIV infection

[a] *Most categories overlap to some extent. For example, increased pulmonary blood flow is usually coupled with anatomic changes in the resistance vessels to produce pulmonary hypertension.*

to vasoconstriction/dilation, these same factors influence cell proliferation and thrombosis. Deficiencies in the production of the potent vasodilators nitric oxide (NO) and prostacyclin have each been observed, and indeed both substances have been used as a basis for effective therapies for PAH. Normally produced by vascular endothelial cells, each promotes the formation of cyclic nucleotides (cGMP and cAMP) by pulmonary arterial smooth muscle cells resulting in their relaxation and vasodilation. In addition, both prostacyclin and NO inhibit pulmonary arterial smooth muscle cell proliferation and platelet aggregation. In patients with PAH, the chronic administration of prostacyclin analogues improves hemodynamics, exercise capacity, and survival. The overexpression of NO synthase (NOS) by transgenic animals protects against the development of hypoxia-induced pulmonary hypertension, whereas mice lacking the gene for this enzyme develop severe pulmonary hypertension upon exposure to mild hypoxia.[60–62] In rats, monocrotaline-induced pulmonary hypertension can be prevented, or even reversed, with the administration of endothelial progenitor cells overexpressing human endothelial NOS (eNOS).[63] Inhaled NO has been proposed for the treatment of PAH and persistent pulmonary hypertension of the newborn;[64] however, inhaled NO has limitations regarding dose and duration of the exposure.[65] The inorganic anion nitrite (NO_2^-) is an oxidative product of NO metabolism and can function as an intravascular reservoir of NO bioactivity that can be converted to NO under physiologic and pathologic conditions.[65] Studies have shown that inhaled nebulized nitrite can prevent and reverse established pulmonary hypertension in the monocrotaline-induced rat pulmonary hypertension model.[66,67]

Vasoactive intestinal peptide (VIP) also promotes vasodilation and inhibits smooth muscle proliferation and platelet aggregation. VIP levels are reduced in patients with PAH. In a preliminary study of eight patients with IPAH, treatment with inhaled VIP improved hemodynamics and exercise capacity.[68] The acute effect of inhaled VIP was confirmed in a subsequent study that included patients with multiple etiologies of pulmonary hypertension including IPAH, congenital heart disease, CTEPH, and pulmonary hypertension related to parenchymal lung disease, although the modest effect on hemodynamics had questionable clinical relevance.[69] A subcutaneous, sustained-release VIP analogue is being investigated for the treatment of PAH.

■ Increase in Vasoconstriction Mediators

In addition to deficiencies in vasodilators, excesses of other mediators capable of promoting vasoconstriction, smooth muscle proliferation, or platelet aggregation have been noted in patients with PAH. Thromboxane, an arachidonic acid metabolite produced by endothelial cells and platelets, causes vasoconstriction and platelet aggregation, and is a smooth muscle mitogen. Increased thromboxane metabolites have been documented in the urine of patients with PAH.[48] Attention was focused on the effects of serotonin (5-HT) on the pulmonary circulation by the epidemic of PAH in patients who ingested the appetite suppressants aminorex and fenfluramine.[70] These agents increase plasma 5-HT levels by inducing the release of 5-HT from platelets and interfering with its reuptake.[71] The 5-HT hypothesis was supported by the occurrence of pulmonary hypertension in fawn-hooded rats with an inherited defect in the platelet storage of 5-HT, and by an increase in circulating 5-HT in a patient with platelet storage disease and PAH.[72] 5-HT causes vasoconstriction and is a smooth muscle mitogen (Fig. 72-4). A key regulator of 5-HT action is the 5-HT transporter (5-HTT) whose expression is increased above normal in platelets and pulmonary arteries of patients with IPAH. The overexpression of the 5-HTT gene in recombinant mice results in worsened hypoxia-induced pulmonary hypertension,[73] whereas loss of the gene's function is protective against hypoxia or monocrotaline-induced disease.[74,75] A polymorphism in the 5-HTT gene that increases its activity may confer an increased susceptibility to the development of pulmonary hypertension in patients with COPD.[76] While some studies have suggested a similar role in IPAH,[77] larger data sets have not found such an association.[78] Blockade of the 5-HT receptor has successfully prevented the development and progression of experimental pulmonary hypertension in rats, yet a human trial was not able to show significant decreases in PVR.[79,80]

Endothelin 1 (ET-1) is one of the most potent endogenous vasoconstrictors yet discovered. Its expression is increased in the blood and tissues of patients with idiopathic and other forms of PAH and correlates with disease severity.[81–83] In addition to its vasoconstricting properties, ET-1 is mitogenic for both pulmonary arterial smooth muscle cells and fibroblasts (Fig. 72-4).[84,85] ET-1 administration or overexpression in animal models has been shown to result in fibrosis, inflammation, and platelet aggregation.[86,87] ET-1 binds endothelin A (ET_A) and B (ET_B) receptors on the surface of pulmonary arterial smooth muscle cells, resulting in potent vasoconstriction. In contrast, ET_B receptors on pulmonary arterial endothelial cells increase the production of nitric oxide, resulting in vasodilatation. ET_B receptors are also active in the clearance of endothelin. The net effect of endothelin's vasoconstricting or dilating actions may be both site and context dependent, as both the distribution and relative expression of the ET_A and ET_B receptors differ according to vessel location in normal lung tissue, and are altered in patients with IPAH.[88,89] Indeed, both selective ET_A and dual ET_A/ET_B inhibition improve the hemodynamic derangements and clinical outcome of patients with PAH.[90–92]

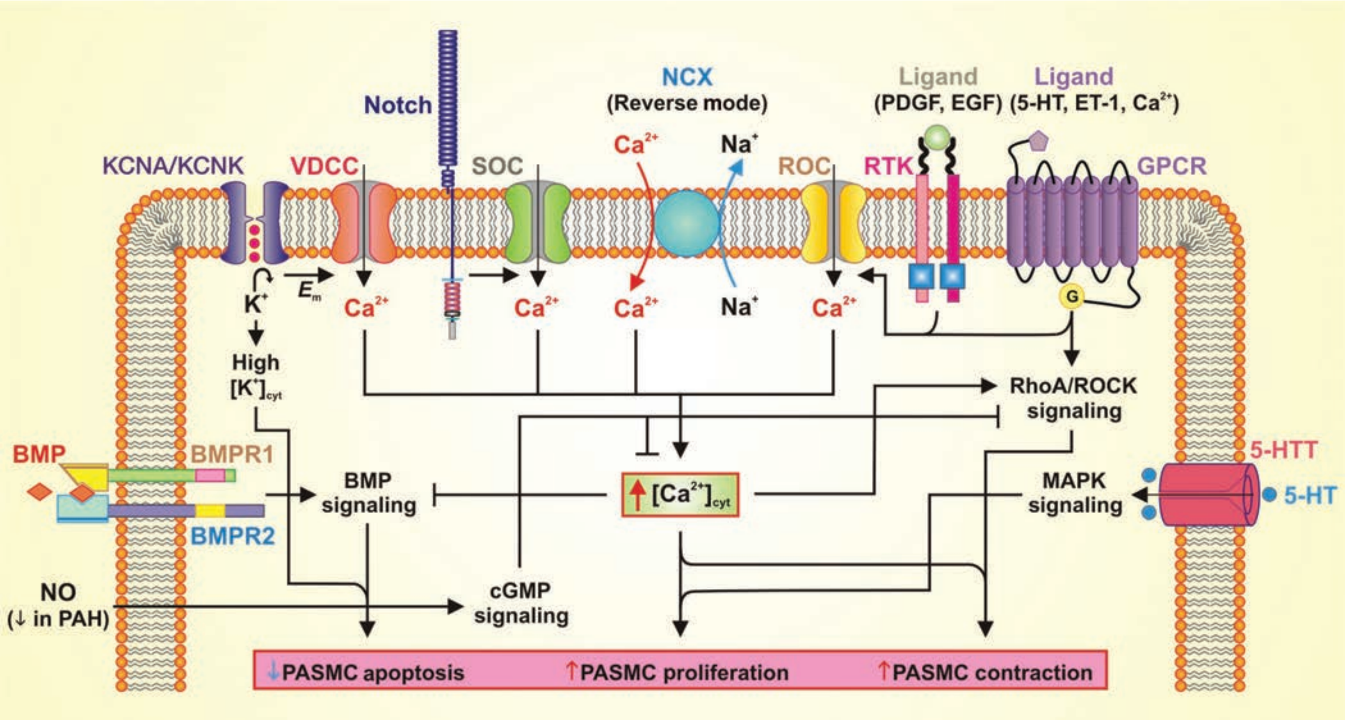

Figure 72-4 Potential mechanisms involved in the development of pulmonary arterial hypertension. Schematic diagram depicting potential mechanisms involved in the development of pulmonary arterial hypertension. BMP, bone morphogenic protein; BMPR, bone morphogenic protein receptor; cGMP, cyclic guanosine monophosphate; E_m, membrane potential; ET-1, endothelin 1; EGF, epidermal growth factor; GPCR, G protein–coupled receptor; 5-HT, hydroxytryptamine (serotonin); 5-HTT, hydroxytryptamine (serotonin) transporter; KCNA, voltage-gated K^+ channel; KCNK, two-pore domain K^+ channel; MAPK, mitogen-activated protein kinase; NO, nitric oxide; NCX, Na^+/Ca^{2+} exchanger; PAH, pulmonary arterial hypertension; PASMC, pulmonary arterial smooth muscle cell; PDGF, platelet-derived growth factor; ROC, receptor-operated Ca^{2+} channel; RTK, receptor tyrosine kinase; SOC, store-operated Ca^{2+} channel; VDCC, voltage-dependent Ca^{2+} channel.

■ Increased Expression of Growth Factors

Growth factors that promote the maturation and stabilization of the developing vasculature have also been implicated in the pathogenesis of PAH. Elevations in angiopoietin 1 and its ligand TIE2 correlate with disease severity in patients with multiple forms of PAH.[93] Angiopoietin 1 is overexpressed in most forms of nonfamilial PAH;[93,94] however, how angiopoietin becomes elevated in these patients is not clear. Several lines of evidence suggest that angiopoietin 1 regulates pulmonary arterial smooth muscle cell hyperplasia in PAH.[9] Interestingly, in an animal model of PAH induced by monocrotaline, the overexpression of angiopoietin is actually protective.[95] Whether this discrepancy represents differences in human versus animal tissues or the differing insults to the vasculature involved is not clear. Another modulator of development, VEGF and its target tyrosine kinase receptor, are increased in the pulmonary vasculature of patients with PAH. Increased VEGF expression has been reported specifically within plexiform lesions[34,96] where its proangiogenic properties are hypothesized to mediate disordered endothelial cell proliferation.[97] Whether such changes are primary, secondary, or indeed detrimental is not entirely clear. Like elevations in angiopoietin, increases in the expression of VEGF thought to be deleterious in some situations might be beneficial in others that promote the development of pulmonary hypertension. In animal models of hypoxia, the inhibition of VEGF signaling results in proliferative vascular abnormalities,[98] and promotion of VEGF signaling is protective against the development of monocrotaline-induced PH.[99]

PDGF along with its receptor, tyrosine kinase, are also found to be increased in the pulmonary vasculature of patients with PAH (Fig. 72-4).[100] PDGF has been implicated in smooth muscle cell proliferation and migration, which is thought to contribute to PAH pathogenesis. The tyrosine kinase inhibitor imatinib has a particular affinity for the PDGF receptor, and several small studies have identified a potential benefit in PAH patients.[101] The IMPRES study with imatinib therapy showed improvements in exercise capacity and hemodynamics in patients with advanced PAH, but serious adverse events including multiple cases of subdural hematoma were observed in the treatment arm.[102] As a result of safety concerns, imatinib has not been approved for the treatment of PAH.

Cellular microparticles recently have been implicated as vasoactive mediators in PAH. Microparticles represent vesicle fragments of the cell membrane containing various proteins and antigens that are involved in cellular communication.[103] These small particles are released during cell activation or apoptosis and can be derived from multiple cell lines including endothelial cells, platelets, leukocytes, red blood cells, and fibroblasts. Circulating levels of endothelial microparticles are increased in PAH, which may represent endothelial dysfunction and has also been correlated with disease survival.[104] Microparticles, when isolated from rats with hypoxia-induced pulmonary hypertension, have been shown to impair endothelium-dependent vasorelaxation in pulmonary arteries and decrease NO production.[105] Circulating microparticles have also been linked to inflammatory signaling in the lung.[106]

■ Increased Cytokines and Inflammation

The close association of systemic inflammatory disorders to IPAH has implicated inflammation as an important factor in vascular remodeling. Numerous cytokines have been implicated in the pathogenesis of PAH including tumor necrosis factor α and interleukins (ILs) 1b, 2, 4, 6, 8, 10, and 12p70. Early data showed increased levels of IL-1β and IL-6 in IPAH patients,[107] and higher IL-6 levels were later found to be associated with mortality.[108] The chemokine fractalkine (CX3CL1) is elevated in CD4 and CD8 T cells of PAH patients, and further studies have shown that CX3CL1 may promote proliferation in pulmonary arterial smooth muscle cells.[109,110] Monocyte chemotactant protein (MCP)-1 is also elevated in serum and lung samples from IPAH patients and may influence monocyte and T-cell recruitment to the diseased lung.[111] Increased expression of Regulated upon Activation, Normal T cell Expressed and Secreted (RANTES) has been found in lung samples from PAH patients.[112] As a chemoattractant for monocytes and T cells, RANTES is thought to promote inflammation but may also play a role in the synthesis of endothelin 1, a potent vasoconstrictor.

FUNCTIONAL CHANGES IN MEMBRANE RECEPTORS AND ION CHANNELS

Important functional changes in membrane receptors and ion channels in IPAH are discussed below.

■ Ca^{2+} Channels in IPAH

Sustained vasoconstriction and vascular remodeling are both directly mediated by pulmonary arterial smooth muscle cell contraction and proliferation. A rise in $[Ca^{2+}]_{cyt}$ due to Ca^{2+} influx through various Ca^{2+}-permeable channels in the plasma membrane is a major trigger for pulmonary arterial smooth muscle cell contraction and a key stimulus for pulmonary arterial smooth muscle cell proliferation.[113] Therefore, understanding how the regulation of Ca^{2+} homeostasis is disrupted in IPAH is important to understanding how IPAH develops. Pulmonary arterial smooth muscle cells isolated from IPAH patients have an elevated $[Ca^{2+}]_{cyt}$.[114–117] Ca^{2+} influx through the plasma membrane in pulmonary arterial smooth muscle cells involves multiple Ca^{2+}-permeable channels including (1) voltage-dependent Ca^{2+} channels (VDCC) regulated by changes in membrane potential,[118] (2) receptor-operated Ca^{2+} channels (ROC) activated by interaction of agonist with membrane receptors, and (3) store-operated Ca^{2+} channels (SOC) activated by depletion of Ca^{2+} from the intracellular stores (Fig. 72-4).[8] Decreased expression and/or function of K^+ channels leads to sustained membrane depolarization, activation of VDCC, and increased $[Ca^{2+}]_{cyt}$. Ca^{2+} influx through ROC, termed receptor-operated Ca^{2+} entry (ROCE), and through SOC, referred to as store-operated Ca^{2+} entry (SOCE), is enhanced in IPAH-associated pulmonary arterial smooth muscle cells compared with those from normal controls.[114–117] Several experimental studies have demonstrated increased expression of several proteins involved in ROCE/SOCE such as TRPC3, TRPC6, STIM2, and Orai2, in pulmonary arterial smooth muscle cells from IPAH patients.[114–117,119,120] In addition, a single-nucleotide polymorphism (SNP) has been identified in IPAH patients that results in enhanced expression and function of TRPC6.[115]

■ K^+ Channels in IPAH

Vascular tone might also be altered in IPAH by changes in the expression of voltage-gated K^+ (Kv) channels as well as other types of K^+ channels (Fig. 72-4). Their activation normally allows an efflux of K^+ and resultant changes in intracellular Ca^{2+} that promote vasodilation.[121] Gene expression of Kv channel family members is downregulated by hypoxia-induced pulmonary hypertension in rats,[122,123] whereas induction of their expression can reverse the hemodynamic effects of hypoxia.[122,124] The expression of specific Kv channels is also decreased in the lungs of patients with IPAH,[125–127] possibly contributing to heightened vasoconstriction resulting from a more depolarized membrane leading to increased $[Ca^{2+}]_{cyt}$ due to activation of VDCC. Kv channels may also mediate the effects of certain drugs. The anorexigens dexfenfluramine and aminorex inhibit smooth muscle Kv channel activity, thus causing pulmonary vasoconstriction.[128] In contrast, enhanced activity of Kv channels may be one mechanism by which sildenafil promotes vasodilation, in addition to its activity as an inhibitor of phosphodiesterase-5.[122] One final way in which decreased activity of Kv channels might promote the development of PAH is by inhibiting apoptosis, thus enabling unchecked pulmonary arterial smooth muscle cell proliferation. Apoptosis requires a loss in cell volume as well as the function of specific caspases, both of which require appropriate K^+ movement via Kv channels.[129,130]

■ G Protein–Coupled Receptors in IPAH

The Ca^{2+}-sensing receptor is a G protein–coupled receptor in the plasma membrane that can be activated by extracellular Ca^{2+} (and Mg^{2+}), polyamines (e.g., spermine), amino acids, and neomycin.[131–134] Activation of the Ca^{2+}-sensing receptor results in activation of intracellular Ca^{2+} signaling pathways that lead to pulmonary arterial smooth muscle cell contraction, proliferation, and migration (Fig. 72-4).[135,136] Like some G protein–coupled receptors coupled to Gq (e.g., endothelin receptors), Ca^{2+}-sensing receptor activation increases the synthesis of inositol 1,4,5 triphosphate (IP_3) and diacylglycerol via phospholipase C. IP_3 binds to the IP_3 receptor on the sarcoplasmic reticulum (SR) membrane and releases Ca^{2+} from the SR to the cytosol. Depletion of Ca^{2+} from the SR induces Ca^{2+} entry via SOCE, and diacylglycerol directly activates ROCE. In addition to increasing $[Ca^{2+}]_{cyt}$ via ROCE and SOCE, the extracellular Ca^{2+}-induced activation of CaSR also activates other signal transduction pathways (e.g., Akt/mTOR and MAPK/ERK) to induce cellular proliferation.[137–139] One study[135] indicated that the extracellular Ca^{2+}-induced increase in $[Ca^{2+}]_{cyt}$ by activation of the Ca^{2+}-sensing receptor is enhanced and the Ca^{2+}-sensing receptor protein expression is upregulated in IPAH-pulmonary arterial smooth muscle cells compared with normal pulmonary arterial smooth muscle cells. These observations suggest that upregulated expression and enhanced function of Ca^{2+}-sensing receptor in pulmonary arterial smooth muscle cells are involved in the development of sustained pulmonary vasoconstriction and pulmonary vascular remodeling in patients with IPAH and animals with experimental pulmonary hypertension. In addition to Ca^{2+}-sensing receptor, many other G protein–coupled receptors are reported to be involved in PAH such as endothelin receptor, prostacyclin receptor, and serotonin receptor.[48,140,141]

■ Na^+/Ca^{2+} Exchanger in IPAH

The Na^+/Ca^{2+} exchanger (NCX) is a ubiquitously expressed protein that transports Ca^{2+} across the plasma membrane along the electrochemical gradient of Na^+ and Ca^{2+}.[142] The NCX can operate in either forward mode, transporting 3 Na^+ ions into the cell and 1 Ca^{2+} ion out of the cell, or the reverse mode, transporting 1 Ca^{2+} ion into the cell and 3 Na^+ ions out of the cell, based on the Na^+ and Ca^{2+} concentration gradients and membrane potential. Due to the reverse mode of the NCX, a small increase in the cytosolic Na^+ concentration ($[Na^+]_{cyt}$) can greatly increase $[Ca^{2+}]_{cyt}$. The canonic transient receptor potential (TRPC) channels, such as TRPC6, which is overexpressed in IPAH patients, are permeable to both Na^+ and Ca^{2+}, and for many TRPC channels, the permeability to Na^+ is greater than the permeability to Ca^{2+}. The reverse mode of the NCX has been shown to couple to TRPC6, and localized increases in $[Na^+]_{cyt}$ result in transport of Ca^{2+} into the cell resulting in increased $[Ca^{2+}]_{cyt}$ in pulmonary arterial smooth muscle cells.[143] The NCX is overexpressed in PASMC isolated from patients with IPAH, and is found localized in caveolae along with other G protein–coupled receptors, ROC, and SOC resulting in a functional coupling of these receptors and contributing to increased $[Ca^{2+}]_{cyt}$, resulting in increased proliferation and contraction of PASCM in patients with IPAH.[116,144]

ALTERED SIGNALING PATHWAYS IN IPAH

Alterations in signaling pathways have been observed in IPAH and are discussed below.

Cyclic Guanosine Monophosphate in IPAH

IPAH is associated with abnormally low levels of the potent pulmonary arterial smooth muscle cell relaxant NO. In pulmonary arterial endothelial cells, NO produced by eNOS freely diffuses across the cell membrane to pulmonary arterial smooth muscle cells and activates intracellular soluble guanylate cyclase (sGC), which catalyzes the conversion of guanosine 5′-triphosphate (GTP) to cyclic guanosine monophosphate (cGMP). cGMP then activates cGMP-dependent kinases, which can reduce $[Ca^{2+}]_{cyt}$, inhibit Rho signaling, and inhibit phosphorylation of myosin-binding protein, all of which lead to smooth muscle relaxation.[145,146] In the lung, metabolism of cGMP is controlled by phosphodiesterase 5 (PDE-5). PDE-5 inhibitors block the breakdown of cGMP, leading to vasodilation due to an accumulation of cGMP in the tissue.[147] In 2005, following several clinical studies, sildenafil was approved for the treatment of PAH.[148] Tadalafil was approved for the treatment of PAH in 2009.[149] Both sildenafil and tadalafil share structural similarities with cGMP and inhibit PDE-5 by competitively binding to the catalytic site.[147]

PDGF and Akt/mTOR Signaling in IPAH

PDGF and its receptor PDGFR have been implicated in the pathogenesis of IPAH. Previous studies have indicated that PDGF increases SOCE in rat and human pulmonary arterial smooth muscle cells, thereby promoting cell proliferation (Fig. 72-4).[119,150] Binding of PDGF to PDGFR leads to activation of phosphatidylinositol 3-kinase (PI3K),[151] which activates Akt. Akt promotes cell growth through the downstream mediator mammalian target of rapamycin (mTOR) or by directly phosphorylating proteins involved in cell cycle regulation and apoptosis.[152] The Akt/mTOR pathway has been shown to be important for pulmonary arterial smooth muscle cell proliferation[150,153] and the development of PAH.[154] Inhibition of mTOR and Akt by rapamycin and Akt inhibitor VIII, respectively, abrogated the PDGF-induced increased SOCE and Ca^{2+} channel expression in normal and PAH-pulmonary arterial smooth muscle cells,[150,155] suggesting that the PDGF-mediated increase in SOCE occurs via the Akt/mTOR pathway.

RhoA/ROCK Signaling in IPAH

The RhoA/ROCK signaling pathway is a major mediator of Ca^{2+}-sensitization/desensitization and a key regulator of vascular tone (Fig. 72-4).[156,157] RhoA is a GTP-binding protein that is activated following activation of G protein–coupled receptors by vasodilators. In addition, RhoA can be activated by serotonin, which enters the cell through its transporter 5-HTT, and by an increase in $[Ca^{2+}]_{cyt}$.[158] Activation of RhoA leads to activation of Rho kinase (ROCK), which increases the Ca^{2+} sensitivity of contraction in pulmonary arterial smooth muscle cells by inhibiting myosin light chain phosphatase and increasing the phosphorylation of myosin light chain kinase, leading to increased contraction of pulmonary arterial smooth muscle cells.[20,21] Recent studies have indicated that the RhoA/ROCK signaling pathway is enhanced in patients with IPAH.[159,160] Small clinical studies have demonstrated that inhibition of the RhoA/ROCK signaling pathway with fasudil, a selective ROCK inhibitor, results in acutely improved pulmonary hemodynamic variables in patients with IPAH.[161,162]

Notch Signaling in IPAH

Notch signaling is involved in vascular development and has been implicated in the development of IPAH (Fig. 72-4).[163,164] Both Notch receptors (Notch1, Notch4) and their ligands, Jagged (Jag1 and Jag2) and Delta-like (Dll1, Dll3, and Dll4), are single-transmembrane–spanning proteins that restrict Notch signaling to adjacent cells. After ligand binding, Notch undergoes a series of proteolytic cleavages resulting in the release of the Notch intracellular domain, which translocates to the nucleus where it interacts with recombination signal binding protein for immunoglobulin kappa j region (RBPjκ) to function as a transcription factor, resulting in activation of transcription of Notch target genes.[163,165–167] The most commonly induced Notch target genes are the basic helix–loop–helix transcriptional repressors of the *Hes* (*Hairy/Enhancers of Split*) and *Hrt* (*Hes-related transcription factor*) gene families. In addition, Notch signaling has been shown to upregulate expression of PDGFR-β,[168] which is known to be upregulated in IPAH.[155,169] Notch3 signaling has recently been implicated in PAH. Lung tissue from IPAH patients displays increased Notch3 and Notch3 intracellular domain (N3ICD) expression when compared with normotensive patients.[164] In addition, Notch3 and N3ICD expression is increased in two animal models of pulmonary hypertension, hypoxic-induced pulmonary hypertension in mice and monocrotaline-induced pulmonary hypertension in rats.[164] This suggests that the Notch signaling pathway may be an important pathway to target for the development of new drugs for the treatment of IPAH.

GENETIC ALTERATIONS RELATED TO IDIOPATHIC AND HERITABLE PAH

Identification of bone morphogenetic protein receptor II (BMPR2) gene mutations has led to increasing interest in genetic susceptibility to pulmonary hypertension. As a receptor for the TGFβ super family, BMPR2 is involved in diverse cell growth and differentiation processes in multiple systems. Engagement of a BMP receptor with its ligand normally results in the activation of intracellular mediators (Smads) and their translocation to the cell nucleus and regulation of the transcription of target genes. The resulting activation of some genes and the inhibition of others varies according to the BMP pathway and tissue involved. BMP signaling is essential to both normal vascular development and the maintenance of the normal adult pulmonary vasculature, likely by regulating the growth and apoptosis of endothelial and smooth muscle cells (Fig. 72-4). Loss of such regulation gives rise to pulmonary hypertension.[170] Normally found primarily on endothelium and to a lesser extent smooth muscle cells, the expression of BMPR2 is reduced and its function abnormal in patients with various types of PAH, most notably those with mutations of the *BMPR2* gene.[171] The ability of BMP to inhibit smooth muscle proliferation and induce apoptosis is suppressed in cells isolated specifically from smaller pulmonary vessels in patients with IPAH (e.g., 1–2 mm, where occlusive vascular pathologic changes predominate).[29,172,173] Germline mutations in *BMPR2* have been identified in up to 70% of patients with heritable PAH, and in 20% of patients with IPAH,[174–180] as well as disease associated with anorexigens,[181] congenital heart disease,[182] and pulmonary venoocclusive disease (PVOD).[183] Nearly 300 different mutations of *BMPR2* have been identified.[177]

Further work has identified other genetic alterations in the TGF-β pathway including activin receptor kinase-like 1 (*ALK1*), endoglin (*Eng*), and Smad 8.[184] ALK1 is a receptor for TGF-β and endoglin is its coreceptor, while Smad 8 is a downstream second messenger of BMPR2. Mutations in *ALK1* and *Eng* have been shown to confer susceptibility to the development of PAH in patients with hereditary hemorrhagic telangiectasia.[185,186] In addition, concomitant thrombospondin 1 gene mutation (*THBS1*) has been detected in a small subset of heritable PAH patients with BMPR2 mutations; this mutation has been proposed to further promote pulmonary hypertension development and increase genetic penetrance.[187]

Several other genetic mutations have been more rarely described in heritable PAH. These include alterations in the genes encoding

TABLE 72-3 Presenting Symptom(s) Attributable to PAH

Symptom	Percentage of Patients at Presentation
Abdominal distention	4%
Chest pain/discomfort	2%
Cough	14%
Dizziness/lightheadedness	15%
Dyspnea at rest	11%
Dyspnea on exertion	86%
Edema	21%
Fatigue	27%
Presyncope/syncope	17%
Palpitations	13%

Data from Brown LM, Chen H, Halpern S, et al. Delay in recognition of pulmonary arterial hypertension: factors identified from the REVEAL registry. Chest 2011;140(1):19–26.

TABLE 72-4 World Health Organization Functional Classification of Patients with Pulmonary Hypertension

Class I: Patients with PH but without resulting limitation of physical activity. Ordinary physical activity does not cause undue dyspnea or fatigue, chest pain, or near syncope.

Class II: Patients with PH resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity causes undue dyspnea or fatigue, chest pain, or near syncope.

Class III: Patients with PH resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes undue dyspnea or fatigue, chest pain, or near syncope.

Class IV: Patients with PH with inability to carry out any physical activity without symptoms. These patients manifest signs of right heart failure. Dyspnea and/or fatigue may even be present at rest. Discomfort is increased by any physical activity.

CLINICAL EVALUATION OF PULMONARY HYPERTENSION

The symptoms and signs of PAH are nonspecific, overlapping with many more common entities. As a result, patients experience problematic delays between the time of symptom onset and appropriate diagnosis.[191,192] The problem is often flagged by findings suggestive of pulmonary hypertension on an electrocardiogram or transthoracic echocardiogram. However, there are useful aspects of history taking and physical examination findings that may raise one's suspicion for PAH.

Patient History in Pulmonary Hypertension

Except for mild breathlessness—often attributed to being "out of shape"—PAH is generally asymptomatic until severe. Because of the nonspecific nature of the symptoms (Table 72-3), underrecognition of the disease by healthcare providers, and its confusion with other conditions, a significant delay between the onset of symptoms and the diagnosis of PAH is common. The mean time from symptom onset until PAH diagnosis was more than 2 years in a National Institutes of Health (NIH) registry assembled in the 1980s.[193] Twenty years later, registries in China, France, Germany, and the United States each found that similarly disappointing delays of more than 2 years persist.[192,194–196] As a result, diagnosis is delayed until most patients have severe functional impairment, with more than one-half reporting World Health Organization (WHO) functional class III or IV symptoms (Table 72-4).

Symptoms due to pulmonary hypertension are generally difficult to dissociate from symptoms of underlying pulmonary or cardiac disease. In IPAH, the first symptoms generally occur during exertion, usually as dyspnea and, less often, chest pain, dizziness, or syncope.[197] Dyspnea on exertion is by far the most common presenting complaint. Often, because of the lack of other signs or symptoms, it is attributed to physical deconditioning or anxiety. Other initial complaints, particularly easy fatigability and chest discomfort, are often similarly dismissed. Angina-like or nonspecific chest pain is common in patients with severe pulmonary hypertension and generally attributed to right ventricular overload and myocardial ischemia. Chest pain might also occur due to the extrinsic compression of the left main coronary artery by an enlarged pulmonary artery.[198]

In time, in the absence of amelioration of the pulmonary hypertension, right-sided heart failure evolves. Syncope, or light-headedness on exertion, is a less common but more ominous complication of pulmonary hypertension. It occurs in patients with severe pulmonary hypertension and a fixed low CO. The cause is inadequate cerebral blood flow due to a combination of failure to increase the CO, along with diversion of systemic blood flow toward the exercising muscles. Syncope may also occur at rest in association with the onset of bradycardia, presumably vagal in origin. Hoarseness, due to paralysis of the left recurrent laryngeal nerve, may result from trapping of the nerve between the aorta and the dilated left pulmonary artery (a form of Ortner syndrome). If the right ventricle should fail, lower extremity swelling is common, as are abdominal signs and symptoms including a sensation of "bloating," early satiety, tender hepatomegaly, ascites, and abdominal pain. Symptoms of right ventricular failure and the presence of syncopal events are associated with a worse prognosis. Hemoptysis in the setting of pulmonary hypertension is most often due to pulmonary venous congestion but when mitral stenosis is present, it is generally attributed to bleeding from bronchial veins. Occasionally, hemoptysis occurs in other forms of pulmonary hypertension and may originate in alveolar capillaries, precapillaries, or elsewhere in the pulmonary arterial tree.

Not infrequently, the suspicion of pulmonary hypertension is raised by the presence of a known risk for pulmonary hypertension (e.g., systemic sclerosis) or by serendipitous discovery of right ventricular enlargement by an electrocardiogram or chest radiograph taken for other reasons (Figs. 72-5 and 72-6). Initial recognition of the presence of pulmonary hypertension also frequently occurs in the absence of reported symptoms when an echocardiogram is performed for the evaluation of a murmur. Alternatively, echocardiographic evidence of pulmonary hypertension may be found unsuspectedly when the study is obtained as "routine" evaluation of a patient complaining of any of a number of chest symptoms, including dyspnea. Patients with severe pulmonary hypertension are prone to sudden death, and its occurrence may be the first indication of disease. Death has occurred unexpectedly during normal activities, cardiac catheterization, and surgical procedures, and

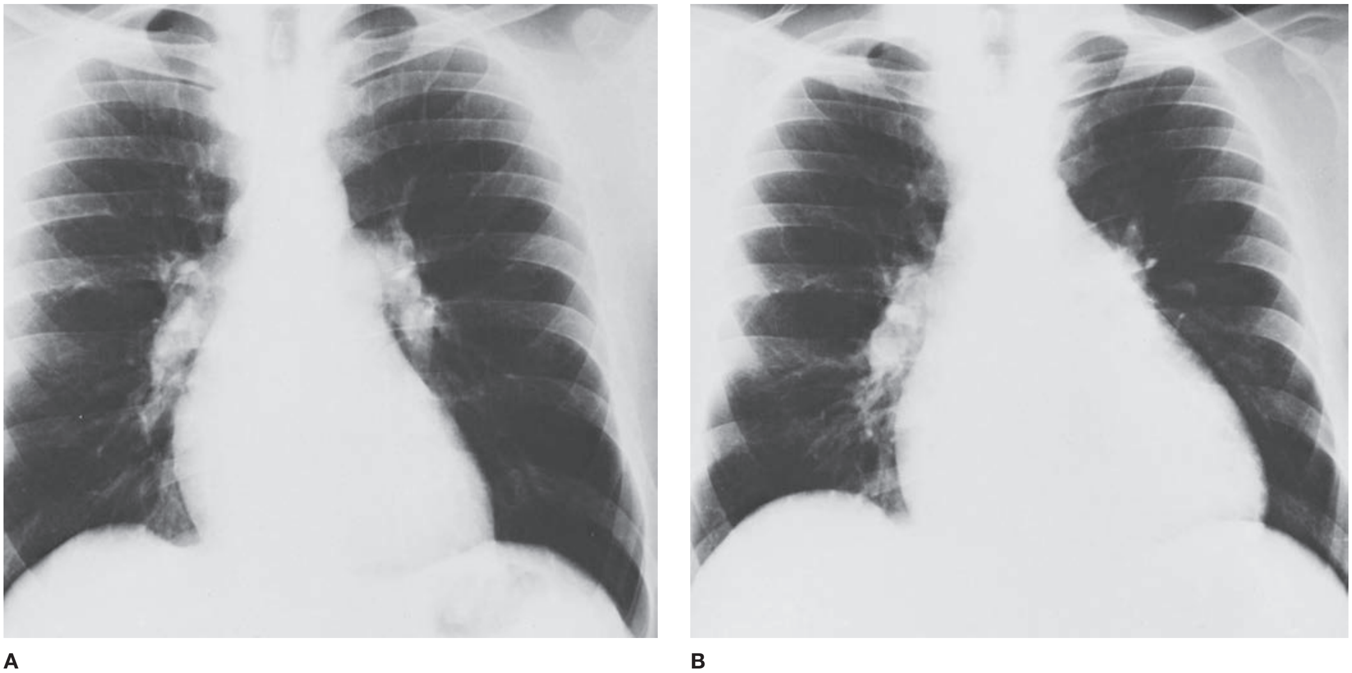

Figure 72-5 Radiographic changes in idiopathic pulmonary arterial hypertension. Compared with a chest radiograph 14 months earlier (**A**), enlargement of the cardiac silhouette has occurred in a 30-year-old man in association with increasing dyspnea (**B**).

after the administration of sedatives or anesthetic agents. In some instances, bradycardia precedes cardiac arrest and death.

An important hint to the presence of pulmonary hypertension is a history of long-standing dyspnea that has not responded to treatment for other more common disorders. Patients have often seen several clinicians before an appropriate diagnosis is made. Younger patients have frequently been told their symptoms are due to asthma, yet failed to improve significantly with aggressive anti-inflammatory and bronchodilator therapies. In older patients, dyspnea or exercise limitation may have been blamed on COPD, often despite a trivial history of tobacco use. Unfortunately, a further clue in such patients is learning that these "diagnostic" labels were never investigated with pulmonary function testing. Patients should be asked about important symptoms or risk factors that might suggest the presence and cause of pulmonary hypertension. These include symptoms of collagen vascular disease (e.g., dysphagia, skin or joint changes, Raynaud's phenomenon), sleep apnea (e.g., witnessed apneic events, daytime hypersomnolence), history of risks for thromboembolism, HIV infection, liver disease, or anorectic agent use. A history of tobacco use and chronic sputum production, or a known history of asthma with poor control, might be important clues to the presence of obstructive airway disease and hypoxia as the cause of pulmonary hypertension. A prior history of interstitial lung disease or any cause of chronic hypoxia must be noted. A careful family history should be taken including inquiring about relatives with poorly understood cardiopulmonary conditions.

■ Physical Examination

A careful physical examination is necessary to recognize the presence of pulmonary hypertension and begin elucidating its cause (Table 72-5). In mild to moderate pulmonary hypertension, the physical examination is apt to be unrevealing unless suspicion has been aroused that pulmonary hypertension may be present. Right ventricular enlargement is an important clue but notoriously difficult to detect in its early stages on physical examination. Evidence of pulmonary hypertension, such as prominent closure of the

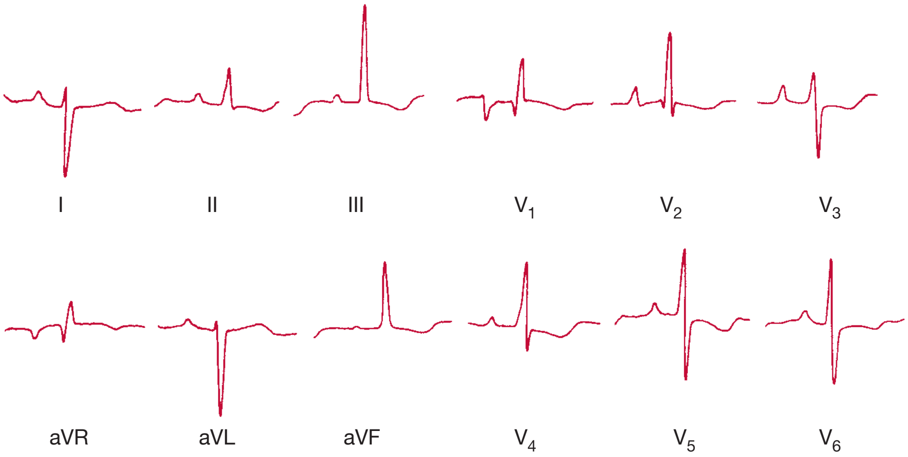

Figure 72-6 Twenty-six-year-old woman in whom the first evidence of idiopathic pulmonary arterial hypertension was by electrocardiography. The record shows marked right axis deviation and dominant R waves over the right precordium consistent with right ventricular hypertrophy.

TABLE 72-5 Physical Examination Findings in Pulmonary Hypertension

Physical Signs that Reflect Severity of PH	
Sign	**Implication**
Accentuated pulmonary component of S2 (audible at apex in over 90%)	High pulmonary pressure increases force of pulmonic valve closure
Early systolic click	Sudden interruption of opening of pulmonary valve into high-pressure artery
Midsystolic ejection murmur	Turbulent transvalvular pulmonary outflow
Left parasternal lift	High right ventricular pressure and hypertrophy present
Right ventricular S4 (in 38%)	High right ventricular pressure and hypertrophy present
Increased jugular "a" wave	Poor right ventricular compliance
Physical Signs that Suggest Moderate to Severe PH	
Sign	**Implication**
Moderate to severe PH	Tricuspid regurgitation
Holosystolic murmur that increases with inspiration tricuspid regurgitation	
Increased jugular "v" waves	
Pulsatile liver	
Diastolic murmur	Pulmonary regurgitation
Hepatojugular reflux	High central venous pressure
Advanced PH with right ventricular failure	
Right ventricular S3 (in 23%)	Right ventricular dysfunction
Distention of jugular veins	Right ventricular dysfunction or tricuspid regurgitation or both
Hepatomegaly	
Peripheral edema (in 32%)	
Ascites	
Low blood pressure, diminished pulse pressure, cool extremities	Reduced cardiac output, peripheral vasoconstriction
Physical Signs that Suggest Possible Underlying Cause or Associations of PH	
Sign	**Implication**
Central cyanosis	Abnormal V/Q, intrapulmonary shunt, hypoxemia, pulmonary-to-systemic shunt
Clubbing	Congenital heart disease, pulmonary venoocclusive disease
Cardiac systolic murmurs, diastolic murmurs, opening snap, and gallop	Congenital or acquired heart or valvular disease
Crackles, dullness, or decreased breath sounds	Pulmonary congestion or effusion or both
Crackles, accessory muscle use, wheezing, protracted expiration, productive cough	Pulmonary parenchymal disease
Obesity, kyphoscoliosis, enlarged tonsils, narrowed pharyngeal opening, macroglossia	Disordered ventilation, sleep apnea
Sclerodactyly, arthritis, telangiectasia, Raynaud phenomenon, rash	Connective tissue disorder
Peripheral venous insufficiency or obstruction	Possible venous thrombosis
Venous stasis ulcers	Possible sickle cell disease
Pulmonary vascular bruits	Chronic thromboembolic PH
Splenomegaly, spider angiomata, palmar erythema, icterus, caput medusa, ascites	Portal hypertension

PH, pulmonary hypertension.

ACCF/AHA 2009 expert consensus document on pulmonary hypertension a report of the American College of Cardiology Foundation task force on expert consensus documents and the American Heart Association developed in collaboration with the American College of Chest Physicians; American Thoracic Society, Inc.; and the Pulmonary Hypertension Association. J Am Coll Cardiol. 2009;53(17):1573–1619.

pulmonary valve, is apt to be overlooked or discounted, especially in younger individuals; recognition of tricuspid insufficiency or a right ventricular gallop is often delayed until pulmonary hypertension becomes severe and has led to heart failure.

Once pulmonary hypertension is suspected, the physical examination can offer important signs. When symptoms first become manifest, a large *a* wave generally can be detected in the jugular venous pulse. Auscultation usually discloses splitting of the second heart sound with accentuation of the pulmonic component. A sharp systolic ejection click over the region of the pulmonary artery is usually heard. As pulmonary hypertension persists, enlargement of the right ventricle becomes evident as a palpable cardiac impulse near the left sternal border and in the hypogastrium. An important sign of more advanced heart failure is a right-sided (ventricular) diastolic

(S_3) gallop; it is accentuated by inspiration. Less helpful is the right atrial gallop (S_4), which occurs immediately before the first heart sound and suggests an increase in the filling pressure of the right side of the heart.

In time, tricuspid insufficiency develops. It is manifested by a holosystolic murmur, best heard in the fourth interspace to the left of the sternum; the murmur characteristically increases in intensity during inspiration (as do the third and fourth heart sounds). A prominent *v* wave appears in the jugular pulse, and distended neck veins pulsate with each heartbeat. The onset of right ventricular failure is often marked by discomfort in the right upper quadrant due to hepatic engorgement as well as edema in the lower extremities. The liver often also shows expansive pulsations that are synchronous with the heartbeat. Hydrothorax and ascites are uncommon, even after right ventricular failure has progressed to the stage of hepatomegaly and pedal edema. Systemic arterial hypoxemia is often present. Assessment of oxyhemoglobin desaturation with activity is an important component of the patient evaluation; if desaturation is noted, formal exercise testing to titrate oxygen therapy should be pursued promptly. Late in the disease, many patients develop peripheral cyanosis secondary to a reduced CO and peripheral vasoconstriction; central cyanosis also occurs preterminally in some patients because of right-to-left shunting through a patent foramen ovale.

The physical examination should be focused on the presence of additional signs to indicate a possible cause of pulmonary hypertension. Systemic hypertension, a risk factor for coronary artery disease or diastolic dysfunction, may suggest left-sided heart disease. Abnormal lung sounds might include wheezing suggesting airflow obstruction, or crackles suggesting either pulmonary edema or diffuse parenchymal lung disease. Additional findings suggestive of lung disease include hyperresonance to percussion or hyperinflation of the thorax (barrel chest) suggestive of COPD or kyphoscoliosis causing a restrictive pattern. Skin changes such as rash or telangiectasias are clues to the presence of collagen vascular disease, as are digital ulcers in patients with the CREST variant of systemic sclerosis. The presence of digital clubbing should also be noted as it may indicate congenital heart disease, certain forms of chronic hypoxic lung disease (e.g., cystic fibrosis or certain interstitial lung diseases), or PVOD.[199] Narrowing of the posterior oropharynx, macroglossia, and a large neck size may suggest obstructive sleep apnea.

■ Diagnostic Studies

Diagnostic testing is used to confirm the presence of pulmonary hypertension, identify the etiology, assess severity and prognosis, and help guide appropriate therapy. Table 72-6 lists tests that are essential in the evaluation of pulmonary hypertension.[200] Table 72-7 lists the criteria required for a diagnosis of PAH.

Following a detailed history and physical examination, an electrocardiogram, chest radiograph, and echocardiogram are indicated if there is suspicion of pulmonary hypertension, and often as logical tests to evaluate symptoms such as dyspnea even if concern for pulmonary hypertension has not been raised.

Chest Radiograph and Electrocardiogram

Early in the evolution of pulmonary hypertension, the chest radiograph appears normal. In time, the central pulmonary arteries become increasingly prominent as the peripheral vessels become

TABLE 72-6 Evaluation of Patients with Pulmonary Hypertension

Detection	Detailed history and physical examination	Suspicion of pulmonary hypertension and possible causes/associations
	Electrocardiogram	Help exclude other causes of cardiopulmonary symptoms
	Chest radiograph	
	Echocardiogram (at rest, to consider repeat with exertion)	Evaluate for presence of pulmonary hypertension, assess chamber sizes and function, valvular abnormalities, contrast (bubble) study to evaluate possible shunt
Essential testing	Pulmonary function testing	Exclude obstructive or restrictive lung disease
	Overnight oximetry	Screen for sleep-disordered breathing
	Lung (V/Q) scan	Exclude thromboembolism
	Blood serologies (e.g., CBC, liver function, renal function, HIV, ANA, antiphospholipid antibodies)	Exclude collagen vascular disease, liver disease, infection, and other possible causes of pulmonary hypertension
	Oxygen desaturation study	Assess need for supplemental oxygen (rest and exertion)
	6-Minute walk test	Establish baseline
	Right cardiac catheterization	Confirm diagnosis, assess other cardiac causes (shunt); consider left heart catheterization
Contingent testing	Transesophageal echocardiogram	Assess for patent foramen ovale, atrial septal defect, abnormal valves, and other abnormalities Characterize valvular function
	Computed tomogram of chest	Assess interstitial lung disease, adenopathy
	Polysomnogram	Diagnosis and treatment of sleep-disordered breathing
	Pulmonary angiogram	Assess presence and location of organized thromboemboli and suitability for pulmonary thromboendarterectomy
	Blood studies (BNP, clotting studies, genetic testing)	
	Lung biopsy	Exclude subtle interstitial lung disease vasculitis and other uncommon diseases (PVOD, PCH) to assist planning

Data from Barst RJ, McGoon M, Torbicki A, et al. Diagnosis and differential assessment of pulmonary arterial hypertension. J Am Coll Cardiol. 2004;43(12 Suppl S): 40S–47S.

TABLE 72-7 Requirements for the Diagnosis of Pulmonary Arterial Hypertension

Required Testing	Rationale
Cardiac catheterization:	Confirm presence of pulmonary hypertension
• A mean pulmonary artery pressure >20 mm Hg • Pulmonary artery wedge or left ventricular end diastolic pressure ≤15 mm Hg • Pulmonary vascular resistance ≥3 Wood units[a]	Exclude left heart disease as the cause of pulmonary hypertension (pulmonary venous hypertension) (group 2 PH)
PFTs, chest imaging without evidence of more than mild lung disease	Exclude chronic hypoxemic lung disease as cause of PH (group 3 PH)
Ventilation–perfusion scan without evidence of unmatched perfusion defects	Exclude chronic thromboembolic pulmonary hypertension (group 4 PH)

[a] *An elevated pulmonary vascular resistance is not included in all published criteria for the diagnosis of PAH.*

attenuated, and the cardiac silhouette enlarges (Fig. 72-7). The chest radiograph (together with pulmonary function tests) may also suggest the presence of underlying lung disease. An electrocardiogram should be obtained and may indicate signs of ischemic heart disease or conduction abnormalities. Findings suggestive of the presence of pulmonary hypertension include right axis deviation, right atrial enlargement, and right ventricular hypertrophy (Fig. 72-6). Arrhythmias are uncommon until late in the course of the disease, when they may contribute to syncopal episodes and coincide with clinical deterioration.

Echocardiogram

When there is suspicion, the echocardiogram is the appropriate first test to assess if pulmonary hypertension is present.[197,201] Indeed, as noted earlier, the unsuspected finding of pulmonary hypertension on an echocardiogram often first brings the issue to attention. A carefully performed Doppler examination is able to quantify the tricuspid regurgitant jet in the majority of cases.[202] A modified Bernoulli equation is used to estimate right ventricular systolic pressure (RVSP = $4v^2$ + right atrial pressure; v = tricuspid jet velocity in meters per second) and is assumed equal to the pulmonary artery systolic pressure when the pulmonic valve is normal. Normal RVSP has been reported as 28 ± 5 mm Hg. Echocardiographic evaluation with exercise is an additional consideration when estimates of RVSP at rest are normal and there is a high suspicion of pulmonary hypertension (e.g., dyspnea in a patient with systemic sclerosis and no other obvious cause). Echocardiographic measurements taken at peak exercise may reveal undue elevations, perhaps signaling the presence of earlier disease. However, normative echocardiographic values of RVSP with exercise have not been well established and whether patients with "exercise-induced" pulmonary hypertension require or benefit from therapies useful for patients with resting pulmonary hypertension is debated.

The echocardiogram also reveals important anatomic and functional information that may assist in identifying the cause of

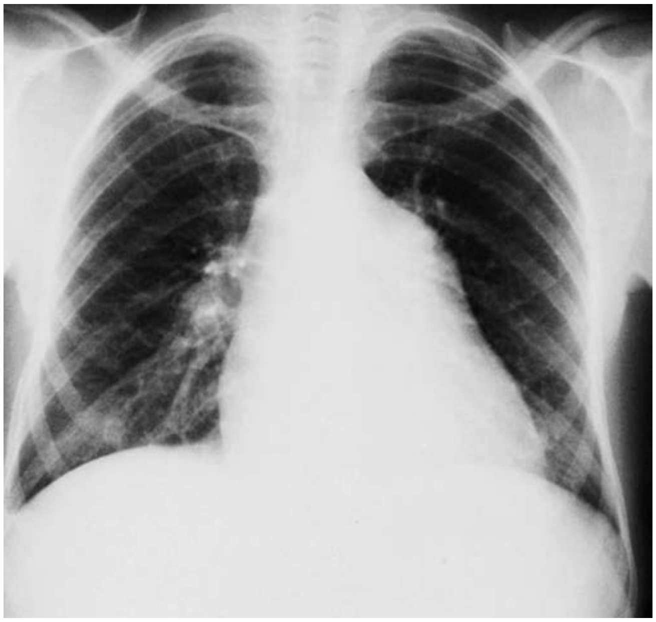

Figure 72-7 Chronic thromboembolic pulmonary hypertension. Prominent central pulmonary arteries in conjunction with the marked pruning of the peripheral tree reflect marked pulmonary hypertension in a patient with a history of multiple pulmonary thromboemboli.

TABLE 72-8 Potential Causes of Pulmonary Hypertension That May Be Identified by Echocardiography

Conditions that Predispose to Pulmonary Hypertension
Congenital or acquired valvular disease (MR, MS, AS, prosthetic valve dysfunction)
Left ventricular systolic dysfunction
Impaired left ventricular diastolic function (hypertensive heart disease, HCM, Fabry disease, infiltrative cardiomyopathies)
Other obstructive lesions (aortic coarctation, supravalvular AS, subaortic membrane, cor triatriatum)
Congenital disease with shunt (ASD, VSD, coronary fistula, patent ductus arteriosus, anomalous pulmonary venous return)
Pulmonary embolus (thrombus in IVC, right-sided cardiac chamber, or PA; tricuspid or pulmonic valve vegetation)
Pulmonary vein thrombosis/stenosis
Findings that Suggest Specific Disease Entity
Left-sided valve changes (SLE, anorexigen use)
Intrapulmonary shunts (hereditary hemorrhagic telangiectasia)
Pericardial effusion (IPAH, SLE, systemic sclerosis)

J Am Coll Cardiol. 2009;53(17):1573–1619.

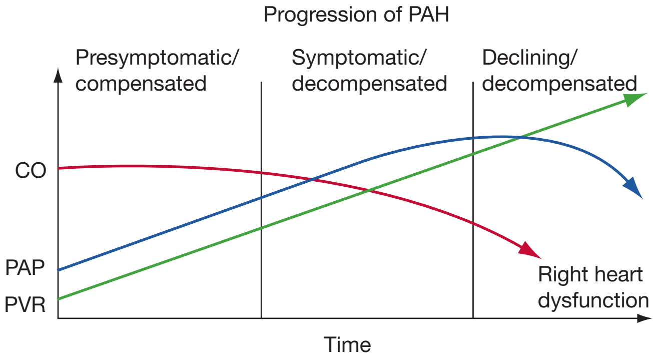

Figure 72-8 Hemodynamic changes during the progression of pulmonary arterial hypertension. With progressive increase in the pulmonary vascular resistance (PVR), the pulmonary artery pressure (PAP) initially increase until a failing right heart can no longer generate the required pressures to maintain cardiac output (CO). At this late stage both the cardiac output and pulmonary pressures may fall. *(Reproduced with permission from Taichman DB: Pulmonary Vascular Disease. Philadelphia, PA: WB. Saunders; 2006.)*

pulmonary hypertension (Table 72-8). Evaluation for a patent foramen ovale and intracardiac or intrapulmonary shunting of blood should be performed (e.g., using "bubble" contrast). Echocardiography can help to rule out related anatomic abnormalities, such as acquired or congenital mitral valve disease or left atrial myxoma. Left ventricular hypertrophy, signs of diastolic noncompliance, decreased systolic function, or focal hypokinesis as well as mitral or aortic valvular defects all are vital observations when evaluating the likely cause of pulmonary hypertension. Assessment of right ventricular size and function is essential, as the symptoms caused by pulmonary hypertension and the prognosis of patients with PAH are determined in large measure by the status of the right heart (Fig. 72-8). Indeed, unexplained echocardiographic findings of RV dilation and/or decreased function warrant further investigation regardless of whether pulmonary hypertension appears to be present by echocardiographic estimate. The degree of RV function is often evaluated subjectively, but more quantitative approaches to assessment are becoming more commonly reported, have variably been shown to predict right ventricular output and patient prognosis, and may provide better means of assessing change with disease progression or in response to therapy. Such approaches include evaluation of the tricuspid annular plane systolic excursion, tissue Doppler imaging, and myocardial performance index (Tei-Doppler index).[203] The presence and greater size of a pericardial effusion are also poor prognostic signs.[204–207] Flattening of the intraventricular septum is seen with advanced right heart dilation and failure, and the leftward movement of the septum may impair left ventricular filling (Videos 72-1 and 72-2).

While the correlation between echocardiographic estimates of pulmonary arterial systolic pressure and measurements taken at right heart catheterization is generally good, there is significant variability and confirmation by catheterization is absolutely required when the presence of pulmonary hypertension will influence the approach to treatment. For example, in the setting of some patients with severe COPD in whom an echocardiogram reveals evidence of pulmonary hypertension, confirmation by right heart catheterization might not impact medical therapy. If, on the other hand, there is consideration of surgical interventions for the COPD (e.g., transplantation or volume reduction), confirmation of the presence of pulmonary hypertension with catheterization may be important. When the diagnosis might be PAH, diagnostic catheterization is absolutely required to confirm the diagnosis and to guide appropriate therapy. Cardiac catheterization in the evaluation of pulmonary hypertension is described in the following section.

Video 72-1 Short-axis view of an echocardiogram of a patient with pulmonary hypertension demonstrating flattening of the interventricular septum with bowing toward the left ventricle during diastole. The right ventricle is hypocontractile. A small pericardial effusion is demonstrated as well. **Video 1, still shot 1**: An echocardiogram performed during diastole in the short-axis view demonstrates an enlarged right ventricle (RV), a flattened interventricular septum (IVS) with bowing toward the left ventricle (LV), and a small pericardial effusion (PE). **Video 1, still shot 2**: An echocardiogram performed during systole in the shortaxis view demonstrates an enlarged right ventricle (RV), a flattened interventricular septum (IVS), and a small pericardial effusion (PE). Impaired filling of the left ventricle (LV) during diastole compromises stroke volume. *(Reproduced with permission from Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.) Pulmonary Function Testing, Ventilation–Perfusion Scanning, Sleep Studies

Once echocardiographic evidence of pulmonary hypertension has been established, testing for possible causes is in order. Pulmonary function tests, a radionuclide ventilation–perfusion scan, and overnight oximetry are essential to screen for possible underlying obstructive/restrictive lung disease, occult chronic thromboembolic pulmonary hypertension, and sleep-disordered breathing, respectively. Although computed tomographic (CT) angiography may reveal the presence of organized thrombus and is frequently useful for evaluation of other possible causes of the patient's symptoms, it is less useful to definitively exclude CTEPH. Since a diagnosis of CTEPH as a cause of pulmonary hypertension will markedly alter therapeutic approach, its exclusion with a ventilation–perfusion scan remains an essential test (Fig. 72-9). A history or the presence of examination findings suggestive of sleep-disordered breathing should prompt performance of overnight oximetry and/or polysomnography. Treatment of significant sleep apnea may be all that is required to treat mild pulmonary hypertension in some patients with preserved right ventricular function who are followed closely for compliance and resolution of pulmonary hypertension.

■ Laboratory Testing

Blood tests including HIV antibody, rheumatologic serologies (e.g., ANA), liver function tests, and a complete blood count are essential. Dyspnea due to PAH may be the presenting symptom leading to the initial diagnosis of systemic sclerosis or HIV infection, and the presence of either would alter required therapeutic plans. Abnormal liver function should prompt further evaluation for possible portal hypertension as an explanation for PAH.

Video 72-2 A four-chamber view of an echocardiogram in a patient with pulmonary hypertension. The right ventricle (RV) is enlarged, dilated, and hypocontractile. The right atrium (RA) is enlarged. The interventricular septum (IS) moves paradoxically toward the left ventricle (LV) during diastole, impairing LV filling. A small pericardial effusion (PE) is demonstrated. **Video 2, still shot 1**: An echocardiogram in the four-chamber view demonstrating an enlarged, dilated RV and RA, as well as a relatively underfilled left ventricle LV and a small PE. The moderator band (MB) of the right ventricle is well visualized. *(Reproduced with permission from Drs. Lissa Sugeng and Wassim Fares, Yale School of Medicine.) Video available on AccessMedicine.com.*

Exercise Testing and Assessment of Oxyhemoglobin Saturation

Baseline testing should also include assessments of exercise tolerance and a determination of whether supplemental oxygen is required. A 6-min walk test is a useful means of assessing exercise capacity and prognosis. It may be useful when choosing initial therapy and serial testing can be helpful in evaluating the response to therapy. Measurements of arterial oxyhemoglobin saturation both at rest and with exertion are important to ensure adequate levels are maintained, and to titrate supplemental oxygen appropriately.

Cardiac Catheterization

Right heart cardiac catheterization is required to confirm the diagnosis of pulmonary hypertension, test for important cardiac causes, and in appropriate patients perform acute vasodilator trials to determine an initial approach to therapy. Both to ensure appropriate interpretation and to avoid the need to subject the patient to repeated invasive testing when initial testing is inadequately performed, cardiac catheterization should be performed under the direction of expert operators sufficiently familiar with the evaluation of pulmonary hypertension. Except in those considered to be at very low risk of coronary artery disease, many expert centers also perform a left heart catheterization in all patients. In addition to coronary angiography, measurement of the left ventricular end-diastolic pressure (LVEDP) is important to exclude left atrial hypertension (e.g., as seen in diastolic dysfunction) as an important cause of pulmonary hypertension (pulmonary venous hypertension). Although pulmonary artery wedge pressure (PAWP) is routinely obtained during right heart catheterization, it does not always provide an accurate estimate of LVEDP. To maximize the chance of an accurate measurement, PAWP should be made at end expiration and not on the basis of digitally computed "mean" PAWP.[208,209] The PAWP should be measured with equipment levelled at the midchest position (halfway between the table surface and skin surface at the sternum). Discrepant readings between the PAWP and the LVEDP may occur frequently, and so the need for left heart catheterization to directly measure left-sided pressures should be carefully considered given the therapeutic implications of the findings.[210]

During right heart catheterization, serial measurements of blood oxygen saturation should be performed for evidence of a "step up" in oxyhemoglobin saturation suggesting the presence of left-to-right shunting of blood as an etiology of PAH. Attention should also be paid to the right atrial pressure, as significant elevation has been associated with a poorer prognosis. When suspicion of pulmonary hypertension is high and resting pressures are normal, some centers assess values with exercise (e.g., with serial leg lifts, arm raising with weights, or a stationary bicycle). As noted previously, however, normative values for pressures with exercise have not been well established and whether exercise-induced PAH represents an early stage of disease or alone warrants treatment remains debated.

A diagnosis of PAH requires a mean pulmonary artery pressure greater than 20 mm Hg and an elevated PVR greater than or equal to 3 Wood units. An adequately measured PAWP or a directly recorded LVEDP of less than or equal to 15 mm Hg is required to exclude pulmonary venous hypertension (WHO group 2 disease). The CO is obtained by either thermodilution or use of measured arterial and venous hemoglobin saturations and the Fick principle; the latter is likely more accurate when either significant tricuspid or pulmonary regurgitation is present or the CO is very low. The PVR is calculated as (mean PAP–PAWP)/CO. A normal PVR may be seen if pulmonary hypertension is due to pulmonary venous hypertension, or abnormally high CO (as may occur, for example, in patients with hyperthyroidism, thiamine deficiency, Paget disease of the bone, or arteriovenous fistulae in hereditary hemorrhagic telangiectasia). PH with an elevated CO and normal PVR may also be found in some patients with liver disease (which is to be distinguished from those with PAH associated with liver disease, termed portopulmonary hypertension [POPH] and characterized by an elevated PVR and PH and a variable CO). It must also be noted that although the hemodynamic profile of patients with PAH (an elevated mean PAP with a normal PAWP) may be seen in patients with pulmonary hypertension and pulmonary parenchymal disease (group 3) but pulmonary function testing and chest imaging distinguish these patients from those with PAH.

In patients with PAH, acute vasodilator testing is often performed at the time of right heart catheterization to identify those few patients in whom a trial of treatment with oral calcium channel antagonists is appropriate (discussed below). Agents commonly used for acute vasodilator testing include inhaled nitric oxide, intravenous adenosine, or intravenous epoprostenol.[211–216] Although the definition has varied, the currently accepted definition that requires a decrease in the mPAP of at least 10 mm Hg from baseline to a value less than 40 mm Hg, together with a CO that is unchanged or increased (but not decreased), is generally considered a "positive" acute vasodilator response.[6,197,217]

Acute vasodilator testing can have significant risk when performed incorrectly.[218] It should not be performed when PVOD is suspected, as the inability of the venous system to accommodate an acute increase in flow may precipitate pulmonary edema.[219] Acute vasodilator testing should be performed only at experienced centers and when the results will influence therapy. Patients who do not demonstrate acute vasoreactivity at the time of right heart catheterization should not receive calcium channel antagonist therapy.

EPIDEMIOLOGY OF PAH

Estimates of the incidence of PAH in studies from France, Scotland, Spain, and the United States range between 2.4 and 7.6 cases per million people. Prevalence estimates range between 15 and 26 cases per million people.[192,194,220,221] Overall, PAH appears to occur more frequently among women (around 2:1) and at a mean age of approximately 50. IPAH and PAH associated with connective tissue diseases appear to be the most commonly recognized in published studies, although limited studies suggest that the burden of schistosomiasis-related disease is likely large.

In the largest such study to date, the mean (± SD) age of patients enrolled in a multicenter U.S.-based national registry of 2525 patients with PAH was 50.1 ± 14.4 years and 79.5% were female. Nearly half of the patients were diagnosed with idiopathic disease (Fig. 72-10). It is important to note that 86% of these were prevalent patients, with a mean of almost 3 years from the time of initial PAH diagnosis until enrollment in the study, thus limiting the ability to extrapolate these data to incident disease.[194]

The prognosis of patients with PAH is worse when hemodynamic variables indicate right heart dysfunction (e.g., elevated right atrial pressure or a depressed CI), and varies according to the specific diagnosis, with PAH associated with scleroderma and portal hypertension portending a worse prognosis than other forms of PAH. Although the outlook appears to have improved with advances in disease management and the availability of multiple drug classes for therapy, many patients continue to require consideration of lung transplantation, and many continue to die. Several risk prediction tools have been recently developed, derived using data from both incident and prevalent patients managed with currently available therapies.[222] One such tool derived, validated, and updated with patients in a large U.S.-based cohort is shown in Fig. 72-11. This, as well as other risk prediction models, has been validated in populations from other countries.[222–225]

SPECIFIC PAH DISEASE SUBTYPES

In the sections to follow, the various PAH disease subtypes will be discussed in detail.

■ Idiopathic Pulmonary Arterial Hypertension

IPAH is a rare disease with an estimated incidence of 1 to 2 cases per million in industrialized countries.[226–228] The paucity of numbers of patients with IPAH and the likelihood that diverse causes and pathogenetic mechanisms can produce the same clinical syndrome have complicated descriptions of its natural history. In the past,

Predicting Survival in Patients With Pulmonary Arterial Hypertension: The REVEAL Risk Score Calculator 2.0 and Comparison With ESC/ERS-Based Risk Assessment Strategies. Chest. 2019;156(2): 323–337.)*

certain stereotypes were regarded as the norm: young women with Raynaud syndrome, with acute onset of dyspnea and fatigue, and death within 3 years. Now it is appreciated that even though there is such a subset, prolonged survival in response to medical therapy is not unusual and the disease may affect all ages, both sexes, and different ethnic groups.[229,230]

To overcome the limitations of sporadic reports, the NIH established a nationwide registry in 1981 to collect and analyze data on IPAH (then called PPH). Criteria for entry of a patient into the national registry included normal pulmonary function tests (except for a moderate reduction in diffusing capacity); a right heart catheterization to exclude congenital or left heart disease; perfusion scans and, if inconclusive, pulmonary angiography to exclude CTEPH; and serologic testing to rule out collagen vascular disease. Included in the registry were certain associated diseases, such as hepatic cirrhosis, because the reason for the association was unclear and because of the suspicion that the association might provide a clue to etiology.

By the close of the registry in 1987, data were available on 187 patients.[231] The mean age was 36.4 years and similar for women and men, although the female-to-male ratio was 1.7:1. Few patients were older than 60 years, although race and ethnicity of the cohort was similar to that of the general population. Similar demographic trends have been reported in series from France, Israel, Japan, and Mexico.[228,232,233] Dyspnea was the most common initial symptom, and the mean time to diagnosis among patients in the NIH registry was 2 years.

Prognosis of IPAH

Without effective therapy the prognosis of IPAH is very poor. The median survival of patients in the NIH registry was 2.8 years; estimated survival at 1, 3, and 5 years was 68%, 48%, and 34%, respectively.[231] Similar or even poorer figures have been reported absent effective treatment in other series from various countries.[46,234] Most patients die of right heart failure. The outlook is worse with more advanced symptoms. NIH registry patients with WHO functional classes III and IV symptoms had a median survival of only 31.5 months, compared with 58.6 months in patients with milder impairment (class I or II; Table 72-4). Although the figures have improved, functional status remains a significant indicator of prognosis even with effective advanced therapy.[228,235–237] Functional assessment with a 6-min walk test, for example, is a useful means of following response to therapy and independently predicts prognosis.[236,238–240] Maximal oxygen consumption has also been used to assess response to therapy and can correlate with survival.[240]

On echocardiogram, an enlargement of the right atrium, the presence of a pericardial effusion and its severity are each associated with an increased risk of death.[204–207] A relative increase in the isovolumetric contraction and relaxation times of the RV as compared with RV ejection time is indicative of RV dysfunction and a significantly poorer prognosis.[241]

Levels of endothelin, catecholamines, and atrial natriuretic peptide have been correlated with disease severity, whereas elevations of uric acid, von Willebrand factor, D-dimer, troponin-T, and brain natriuretic peptide have each been associated with a poorer survival in patients with IPAH.[242–248] More recently, a low serum albumin has been associated with an increased risk of death, independent other measures that would reflect passive hepatic congestion or right heart dysfunction.[207] None of these putative prognostic markers is currently incorporated into clinical decision-making.

Hemodynamic variables reflecting the development of right heart failure (an increased right atrial pressure and decreased cardiac index) are associated with a poorer prognosis.[233,249,250] Worsened survival has been seen in association with both increasing and decreasing mean pulmonary artery pressures (mPAPs). These observations are not necessarily contradictory. Rather, they reflect the natural history of right heart failure in PAH: mPAP rises initially as the vascular derangements worsen only to fall later as the right heart fails and is no longer able to generate an increased pressure (Fig. 72-8).

A regression equation based on hemodynamic data from the NIH registry has been used to predict survival.[233,251] Because of the dismal prognosis expected, long-term "control" groups without treatment in clinical trials are unethical and assessments of survival with new therapies have been compared with outcome as predicted by the NIH equation. Such comparisons have suggested improved survival with epoprostenol and endothelin receptor antagonists. These improvements are addressed in the discussion of individual therapies in the following sections. As a growing number of effective drugs are now routinely employed, the relevance of survival estimates based on data from an era lacking effective treatment is questionable. The NIH registry equation is no longer sufficient for predicting survival given current standards of care and background therapies. When applied to a more recent cohort of patients treated with current agents, the NIH equation underestimated survival.[207]

It is not surprising that the prognosis of patients with IPAH who have suffered cardiac arrest is dismal even when resuscitative efforts are initiated promptly. In a retrospective review of the records of over 3000 patients, 132 episodes of attempted cardiopulmonary resuscitation (CPR) following cardiac arrest were identified. Survival at 90 days following CPR was only 6%.[252]

■ Heritable Pulmonary Arterial Hypertension

A family of patients with what was then termed "PPH" was first described by Dresdale in 1951.[4] Thereafter additional families were reported, and Loyd and Newman identified an autosomal dominant pattern of inheritance, a greater tendency for female carriers to manifest clinical disease, and an earlier onset in successive generations (genetic anticipation).[253,254] Linkage analysis led to a marker at chromosome 2q31–32, and mutations in the gene for a member of the TGF-β family of receptors, bone morphogenetic protein receptor II (BMPRII), were identified as the cause of heritable PAH.[175,176,255,256] In addition, concomitant thrombospondin 1 gene mutation (*THBS1*) has been detected in a small subset of heritable PAH patients with BMPR2 mutations; this mutation has been proposed to further promote pulmonary hypertension development and increase genetic penetrance.[187]

Mutations in another member of the TGF-β family, ALK1, predispose patients with hereditary hemorrhagic telangiectasia to develop PAH.[185,186,257,258] Several other genetic mutations have been more rarely described in heritable PAH. These include alterations in the genes encoding 5-hydroxytryptamine (serotonin) transporter, mothers against decapentaplegic homologue 9 (SMAD9), caveolin 1, and potassium channel subfamily K member 3 (KCNK3).

TGF-β receptors control an array of cell growth and differentiation systems. BMP signaling is involved in the control of normal vascular development as well as the homeostasis of the adult pulmonary vasculature, likely by regulating the growth and apoptosis of endothelial and smooth muscle cells.[170] In an assessment of mutations from the coding sequence of *BMPRII* in 210 patients, more than 140 distinct mutations were identified, the majority predicting premature truncation of the gene transcript. Disease is believed to result from haploinsufficiency, where inadequate quantities of BMPR2 protein are produced for normal function.[177] In addition, the low penetrance observed in heritable PAH suggests that additional environmental factors likely contribute to disease development in genetically susceptible individuals.[259] Up to 70% of patients with heritable PAH have germline mutations in a *BMPRII* allele, as do some patients with idiopathic and other associated forms of PAH.[175,176,178–183] Clinically asymptomatic carriers may have evidence of mild pulmonary hypertension on echocardiogram.[260] Common ancestries have been identified that link previously assumed "sporadic" cases of IPAH. Failure to recognize heritable cases of PAH may arise due to incomplete family history taking or reporting, and low disease penetrance, particularly in smaller families.[179,261]

There are no established differences in the approach to treating patients with heritable PAH compared with IPAH. At present, the clinical evaluation of patients remains the same. Genetic testing of family members should be considered to assess the risk of developing PAH. As a rough guide, there is a one in five chance of PAH developing in a first-order relative who carries a disease-causing *BMPRII* mutation. If genetic testing has not been performed, the risk of disease developing in the first-order relative of a patient with known heritable PAH is approximately one in ten. In the absence of a disease-causing *BMPRII* mutation, the risk of disease is the same as in the general population (estimated at one in a million).[259] Because of the potential interpersonal, psychological, and economic implications of identifying an at-risk genotype, genetic testing should be performed only in conjunction with professional genetic counselling.

■ Pulmonary Arterial Hypertension Associated with Specific Conditions

Pulmonary arterial hypertension has been reported in a wide variety of disorders, as discussed below.

Connective Tissue Disease

The lungs and the pleura are commonly affected in patients with connective tissue disease. Although the incidence in each of the connective tissue diseases varies, interstitial lung disease is more common than isolated involvement of the pulmonary vasculature. When present, however, PAH is frequently a more rapidly lethal development than interstitial lung disease. It is important in this population to differentiate between pulmonary hypertension associated with interstitial lung disease and the true development of PAH that occurs in the absence of significant interstitial changes. Pulmonary hypertension may also develop due to left heart ischemia or diastolic dysfunction, or to thromboembolic complications of collagen vascular disease.[262] Unfortunately, both interstitial lung disease and true PAH coexist in many patients. Most clinical studies of PAH therapy have excluded patients with collagen vascular diseases and evidence of "significant" restriction (usually defined as an FVC of <70% of predicted values) or interstitial changes on radiographs. Drugs that are efficacious in PAH have not proved effective in the treatment of pulmonary hypertension that accompanies interstitial lung disease. Among patients with systemic sclerosis, PAH occurs most commonly in those with limited disease or the CREST syndrome. Prevalence estimates have ranged significantly, but when investigated with right heart catheterization, PAH has been found in 7% to 12% of patients.[263,264] The prognosis of patients with scleroderma is worse when their disease is complicated by PAH than by pulmonary fibrosis, even when the latter is severe. Nearly one-half of patients with PAH in the context of scleroderma die within 1 year, compared with a 3-year 50% mortality when the lung is affected by fibrosis alone.[265,266] Even with the use of equivalent therapies, the outcome of patients with PAH associated with systemic sclerosis is less favorable than for IPAH (Fig. 72-12).[90,235,265,267,268]

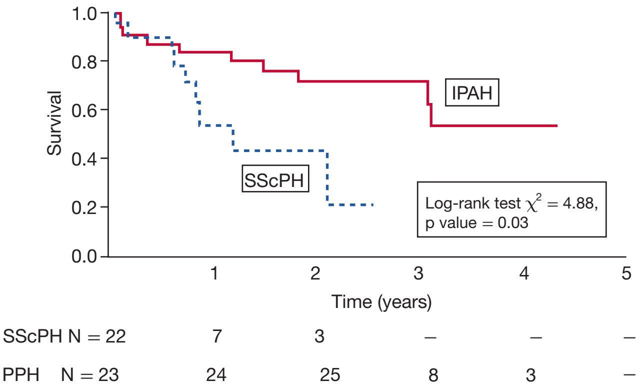

Figure 72-12 Survival of patients with systemic sclerosis–associated pulmonary arterial hypertension is worse than that of patients with idiopathic pulmonary arterial hypertension despite equivalent therapies. *(Reproduced with permission from Kawut SM, Taichman DB, Archer-Chicko CL, et al. Hemodynamics and survival in patients with pulmonary arterial hypertension related to systemic sclerosis. Chest. 2003 Feb;123(2):344–350.)*

When estimated by echocardiography, pulmonary hypertension has been identified in approximately 4% to 10% of patients with systemic lupus erythematosis, but as many as 43% when patients are followed prospectively.[269–274] Estimates of prevalence are variable and most were obtained without confirmation by catheterization in patients with mixed connective tissue disease. Regardless of frequency, however, when it is present, PAH appears to be a significant cause of death in these patients. PAH occurs in numerous other rheumatologic disorders, including Sjögren syndrome and rheumatoid arthritis, although firm data on incidence or impact on survival are lacking.

Human Immunodeficiency Virus

Patients infected with the human immunodeficiency virus (HIV) are at increased risk of developing PAH. The mechanism by which HIV predisposes to the development of PAH is not known, but it does not appear to be due to direct viral infection of pulmonary vascular endothelial cells.[275] Infection may cause elevations in local concentrations of growth factors or other mediators such as endothelin to indirectly result in the development of PAH.[276–278]

The estimated annual incidence of PAH among HIV-infected patients is approximately 0.5%, significantly higher than the estimated annual incidence of 1.7 per million in the general population.[225,279] The annual incidence of pulmonary hypertension in a large Swiss cohort of HIV-positive patients appears to be declining, having peaked at 0.24% in 1993 as compared with 0.02% in 2001; this decline was hypothesized to relate to the introduction of highly effective antiretroviral therapies.[280] However, no such change was seen in a French study population, comparing rates of HIV-associated PAH between the early 1990s and 2008.[281] It is unclear, therefore, if better control of HIV infection alters the risk of developing PAH.

Symptoms, hemodynamic findings, and survival of PAH associated with HIV appear to be similar to IPAH.[282] Like IPAH, the prognosis is worse with more advanced symptoms (e.g., WHO functional class III or IV compared with either I or II). A CD4 lymphocyte count below 212 cells/mm^3 also has been associated with a poorer prognosis.[283] Mortality is more often directly attributable to PAH and right heart failure than to infectious complications.[282,283]

Portal Hypertension

The lung may be affected by chronic liver disease in several ways, including the hepatopulmonary syndrome with the development of vascular dilatations and resultant hypoxemia, the development of pleural effusions (hepatic hydrothorax), and pulmonary hypertension. Liver disease is frequently characterized by a low systemic vascular resistance and high CO; the accompanying increased flow and blood volume result in pulmonary hypertension although the PVR is normal or even decreased. Vascular changes resulting in an elevated PVR, on the other hand, are seen with the development of PAH associated with portal hypertension, also termed POPH. Evaluation of pulmonary hypertension in these patients may be difficult, as the high CO state of liver disease may precede or accompany the developmental POPH. Thus, compared with patients with IPAH, patients with similar degrees of clinical impairment and POPH may display numerically smaller elevations in PVR or decrements in CO.[284]

The pathologic changes seen in POPH are similar to those described in other forms of PAH: vasoconstrictive, proliferative, and obliterative changes including both plexiform and thrombotic lesions.[285,286] The pathogenesis is not well understood and may involve abnormal proliferative (or other) vascular responses, but inducing triggers are not well defined. Portal hypertension might alter the vasoactive mediators to which the pulmonary circulation is exposed because of blood bypassing the liver via portosystemic shunts and returning to the systemic circulation.[287] As in other forms of PAH, altered levels of vasodilators and vasoconstrictors have been observed in patients with POPH.[288,289] Women with portal hypertension appear to be at greater risk for the development of POPH than men, as do patients with autoimmune hepatitis. The severity of portal hypertension does not appear to influence the risk of POPH.[290,291] Predisposing, likely genetic, factors are also believed to determine why only some patients with liver disease develop POPH.[292] The degree to which mutations in *BMPR2* are involved in the development of POPH remains unclear.

The prevalence of PAH in patients with liver disease has not been established. Estimates of up to 16% have been reported in studies screening patients with advanced liver disease.[288,293] In one series of patients evaluated for liver transplantation, the prevalence of POPH was 8.5%.[285] Incidence has not been evaluated. Without effective treatment the prognosis of POPH is poor, with a mean survival of only 15 months reported in one retrospective series of 78 patients.[294] Survival with current therapies is worse for patients with POPH than IPAH. In the REVEAL cohort, despite less severe hemodynamic derangements at the time of enrollment, 5-year survival of 174 patients with POPH was significantly worse than of 1478 patients with IPAH/HPAH (40% vs. 64%, respectively), although the initiation of therapy appeared to have been delayed in POPH compared with IPAH.[284]

The symptoms and findings on physical examination of POPH reflect the presence of both PAH and chronic liver disease. While shortness of breath may be overshadowed by abdominal complaints and fatigue, dyspnea becomes prominent as POPH progresses. Differentiating between the contributions of PAH-related cor pulmonale and cirrhosis as the cause of fatigue, edema, and abdominal complaints such as satiety, bloating, and ascites can be difficult.

Compared with IPAH, there are a paucity of data regarding effective treatments for POPH, due to the small number of patients with POPH and their exclusion from nearly all PAH clinical trials until the PORTICO study (discussed more below). Mild disease usually does not require specific treatment; whether early therapy will prevent progression is unknown. Treatment for more severe disease differs from that of other patients with PAH in that some experts have advised against the use of calcium channel antagonists even if acute vasoreactivity is documented during cardiac catheterization. This concern is based upon the potential worsening of intrahepatic venous gradients by calcium channel antagonists.[295–298] Diuretics are particularly important in POPH due to the frequent presence of both cor pulmonale and cirrhosis causing fluid retention, edema, and ascites. Anticoagulation is less frequently employed due to pre-existing coagulopathy related to underlying hepatic synthetic deficiencies or the presence of splenomegaly and significant thrombocytopenia.

The experience with currently available PAH targeted agents in the treatment of POPH has been reported in small case series.[299–308] The PORTICO study was the first randomized controlled trial investigating the efficacy and safety of the endothelin receptor antagonist macitentan in patients with POPH.[309] Macitentan improved the primary endpoint of PVR reduction at 12 weeks without significant hepatic safety concerns. These results should not be generalized across other endothelin receptor antagonists due to known association of liver function abnormalities with bosentan and differing mechanism of action with the selective antagonist ambrisentan.

Many patients with advanced hepatic dysfunction require liver transplantation. The perioperative mortality is significantly increased by the presence of severe PAH, however, and therefore a mean PA pressure above 50 mm Hg is considered a contraindication to transplantation at most centers.[310,311] Effective treatment to lower PAPs has been used in some patients who subsequently underwent orthotopic liver transplantation successfully.[299–302,306,312]

It is therefore essential that POPH be recognized in patients being considered for liver transplantation prior to surgery. All potential liver transplant patients should be assessed by echocardiography, and cardiac catheterization should be undertaken when the estimated right ventricular systolic pressure approaches 50 mm Hg. Serial monitoring for the development of pulmonary hypertension should be performed in patients listed for liver transplantation.[313] Unlike the hepatopulmonary syndrome, in which liver transplantation results in resolution of the pulmonary vascular abnormality, liver transplantation is not reliably curative of POPH. While some cases of reversal have been reported, POPH has progressed in other patients following transplantation.[295]

Drugs and Toxins

The term "dietary pulmonary hypertension" refers to the fact that substances taken by mouth can damage the pulmonary circulation. In animals, ingestion of *Crotalaria spectabilis*, an annual shrub, causes multiorgan injury, including damage to the lungs. In humans, certain appetite suppressant drugs exert similar effects.

Anorectic Agents—Aminorex and Fenfluramine Derivative Between 1966 and 1968, an epidemic of PAH erupted in Switzerland, Austria, and Germany where the incidence increased 20-fold.[314] The epidemic followed the introduction in these countries of an appetite-depressant agent, aminorex (2-amino-5-phenyl-2-oxazoline), in November 1965. Although only 2% of those exposed to the drug developed PAH, the relative risk compared to unexposed individuals was 52:1.[315] Aminorex resembles epinephrine and amphetamine in chemical structure; both of these agents release endogenous stores of catecholamines. Aminorex was banned in 1968, and the epidemic subsided. After stopping the drug, the level of pulmonary hypertension decreased or stabilized at a tolerable level in some patients and completely reversed in others. However, in many patients, the disease continued inexorably from pulmonary hypertension to cor pulmonale and death despite discontinuation of the drug. The pathology produced by aminorex in humans was identical to that of IPAH, including plexiform lesions and intimal fibrosis. Unfortunately, attempts to produce pulmonary hypertension by administering aminorex to experimental animals were consistently unsuccessful.

This outbreak had several important epidemiologic implications: (1) A medication taken by mouth could damage pulmonary arteries and arterioles; (2) because few of the many individuals who used the agent developed pulmonary hypertension, the possibility was raised of genetic susceptibility to injury by aminorex; (3) other anorectic medications that resemble the catecholamines and amphetamines in structure might have similar effects in predisposed individuals (this possibility was reinforced by experience with phenformin, an antidiabetic agent that resembles the amphetamines in structure); and (4) pulmonary hypertension can be reversible, particularly when detected early in its course and before pressures reach systemic levels.

After the aminorex epidemic, a variety of appetite-suppressant medications were used with little heed to the possibility that these agents might cause PAH. Then, in the early 1990s, Brenot et al.[316] called attention to possible association in Europe of PAH and the use of fenfluramine derivatives for weight reduction, prompting the establishment of an international registry in Europe to assess the incidence and risks of IPAH. Among the 95 patients enrolled in the registry, anorectic agent use was clearly associated with an increased risk of PAH, especially when taken longer than 3 months (odds ratio, 23.8). In 1996, Abenheim sounded the alarm that an epidemic might be in the making: the Food and Drug Administration in the United States had approved the use of dexfenfluramine, a fenfluramine derivative, for the long-term treatment of obesity even though experience with long-term use was extremely sparse.[226]

Approval of dexfenfluramine by the FDA was followed by a tremendous increase in sales of this and other anorectic agents. A registry of idiopathic and anorectic agent associated PAH in the United States revealed that use of fenfluramine was strongly associated with the development of PAH (odds ratio, 7.5 with >6 months use). A high prevalence of anorectic agent use in patients with other forms of PAH was also seen, suggesting these agents might also precipitate disease in the presence of other risks such as a collagen vascular disease.[317]

Several points were illustrated: (1) Although aminorex and the fenfluramines differ in their pharmacologic characteristics, the pulmonary vascular lesions in the patients who die of pulmonary hypertension after taking either drug are identical; (2) the longer the anorectic agent is used, the more likely pulmonary hypertension is to develop; and (3) the occurrence of pulmonary hypertension in users of anorectic agents likely is related to other determinants of susceptibility, perhaps genetic.

Aminorex and fenfluramine derivatives may cause PAH by altering blood levels of serotonin (5-HT). These agents cause the release of serotonin from storage in platelets and inhibit its reuptake,[71] and serotonin is a potent vasoconstrictor and induces the aggregation of platelets. An additional mechanism by which aminorex and fenfluramine derivatives might contribute to pulmonary vasoconstriction is via the inhibition of potassium channels that mediate vasodilation.[128] An inductive role of anorexigens in promoting the development of PAH in genetically susceptible individuals also has been hypothesized. Genotyping for the presence of mutations in *BMPRII* (with heritable PAH) has not revealed a significant number of abnormalities among patients with anorexigen-associated PAH.[181,318]

In one series of 62 patients with fenfluramine-associated PAH evaluated over a 10-year period at a single center in France, the interval from drug exposure to the development of dyspnea was approximately 4 years. Hemodynamic values at the time of diagnosis were similar to a control group of patients with IPAH, although the anorectic agent–exposed patients were less likely to demonstrate acute vasoreactivity and thus be treated with calcium channel antagonists.[319] The approach to therapy for PAH associated with anorectic agent use, however, is similar as for IPAH.

Relatively little is known regarding the prognosis of anorectic agent–associated disease. Data conflict regarding prognosis as compared with IPAH. In one retrospective study of 104 patients with aminorex-associated PAH and 69 with IPAH, survival was better in both groups for patients treated with warfarin, and better overall for the anorectic-agent associated disease patients.[320] With the use of advanced therapies, survival in fenfluramine-exposed patients with PAH appears similar to that of IPAH patients.[319] When matched according to treatments and disease severity, however, a separate study of IPAH and fenfluramine-exposed patients found poorer survival in the anorectic agent group.[321]

Toxic Oil Syndrome Another episode of dietary pulmonary hypertension unfolded with the occurrence of the "toxic oil syndrome." In May and June 1981, rapeseed oil adulterated with aniline was sold door to door as olive oil in Spain and caused an outbreak of noncardiogenic pulmonary edema.[322] Twenty thousand persons were affected, and approximately 375 died. About 2000 individuals experienced sequelae. As a consequence of close surveillance, the features of three stages of the disease were categorized as early (first 6 months), intermediate (6 months to 2 years), and chronic (persisting years). From the outset, it was clear that the damage was widespread (affecting lungs, liver, skin, nervous system, immune system, muscle, and fat) and that pervasive endothelial injury featured prominently in the pathogenesis of the clinical syndromes.

The early stage was characterized by noncardiogenic pulmonary edema, eosinophilia, and pulmonary hypertension in a subset of patients; these findings resolved within 6 months. The intermediate stage was marked by thromboembolic events, weight loss, and neuromuscular dystrophies; PAH developed in some but often resolved. The chronic stage (particularly 4 and 5 years after the oil was ingested) involved progressive PAH and cor pulmonale. Increasingly evident were vascular lesions of intimal fibrosis and proliferation in association with organized pulmonary thromboemboli. Plexiform lesions also were seen.

Unfortunately, the exact chemical ingredients in the toxic oil responsible for the syndrome remain enigmatic and are unlikely to be identified, since the bootleggers could provide no recipe for the adulterated cooking oil. Nonetheless, the outbreak did show that material taken by mouth—often in small quantities—could cause widespread endothelial injury in the lungs. It also underscored the spontaneous reversibility of the pulmonary hypertension (as well as the ineffectiveness of vasodilators tried at different stages in the disease).

Hemoglobinopathies

Patients with sickle cell anemia and other hemoglobinopathies are at increased risk for the development of pulmonary hypertension. Pulmonary hypertension in this setting is currently categorized within group 5 disease. Multiple factors likely contribute to the pathogenesis of pulmonary hypertension in patients with hemolytic states, including recurrent thromboembolism, recurrent infectious or hemolytic crises causing lung damage and hypoxia, asplenia, and the microvascular effects of intravascular hemolysis itself. Hemolysis contributes to the development of pulmonary hypertension by reducing the bioavailability of NO. Hemoglobin is released into the plasma from destroyed red blood cells where it can bind and sequester NO. There is also destruction of the substrate for NO production, L-arginine, by increased levels the enzyme arginase, also released into plasma by hemolysis. Further effects of hemolysis include an increase in the expression of vascular adhesion molecules, platelet activation, the production of free radicals, and elevated levels of endothelin, all of which might contribute to the vasculopathy.[323–325]

The reported prevalence of pulmonary hypertension in patients with sickle cell anemia has ranged from 0% to 40%. Factors influencing this wide range include the age of patients examined, whether the study involved asymptomatic or symptomatic patients, and whether testing involved echocardiography or cardiac catheterization. In one prospective study of 195 adult patients with sickle cell anemia, 32% of patients had echocardiographic evidence of pulmonary hypertension, of whom more than 90% had the SS phenotype.[326] Pulmonary hypertension is associated with a poorer prognosis in patients with sickle cell anemia.[323,326] Pulmonary hypertension has also been noted in patients with other chronic hemolytic disorders, including thalassemias, hereditary spherocytosis, and paroxysmal nocturnal hemoglobinuria.[327–332]

The hemodynamic findings of pulmonary hypertension associated with sickle cell anemia differ from those seen in patients with idiopathic or other forms of associated PAH. Specifically, the mean PAP tends to be lower and CO higher in patients with sickle cell anemia diagnosed with pulmonary hypertension than in patients with IPAH. In addition, many patients with hemoglobinopathy and pulmonary hypertension demonstrate a combination of intrinsic pulmonary vascular disease suggested by an elevated vascular resistance together with left heart diastolic dysfunction with an elevated PAWP.[333] As an example, in 20 patients with pulmonary hypertension associated with sickle cell anemia the mean PAP was 36 mm Hg, CO 8.6 L/min, and PAWP 16 mm Hg; one-half of the patients had PAWP values above 15 mm Hg.[334]

The optimal treatment of patients with pulmonary hypertension associated with a hemoglobinopathy has not been established. As markers of ongoing hemolysis correlate with the severity of pulmonary hypertension as well as survival in patients with sickle cell disease, maximizing treatment of the hemolytic anemia is likely an important therapeutic consideration.[323,326] Treatment includes the use of hydroxyurea or transfusions to minimize anemia and ongoing hemolysis. Supplemental oxygen to prevent hypoxia should be used as in other forms of pulmonary hypertension. While not studied in patients with hemoglobinopathy for treatment of pulmonary hypertension itself, anticoagulation to prevent thromboembolic complications of sickle cell anemia is also a consideration. Intravenous prostacyclin can acutely decrease the mean PAP and PVR in patients with PAH associated with sickle cell anemia, but its long-term benefits have not been established.[334] Improvement with oral sildenafil was initially reported in small, uncontrolled series of sickle cell anemia patients.[335,336] However, a larger randomized controlled trial in sickle cell anemia and PH (Walk-PHaSST trial) was halted due to increased rates of pain crises and hospitalizations in the sildenafil group with no appreciable difference observed in exercise capacity.[337]

■ Pulmonary Venoocclusive Disease

PVOD is a rare form of PAH in which there is even less understanding of mechanisms and less experience with therapy.[219,338] PVOD and pulmonary capillary hemagiomatosis (discussed below) are believed to represent closely related and at times overlapping conditions. Some combination of pathologic changes on both the arterial and venous sides of the pulmonary circulation is found in all forms of PAH, but arterial changes tend to predominate in most cases. There is patchy occlusion of pulmonary veins by fibrous tissue, intimal thickening, and large numbers of hemosiderin-laden macrophages. Lymphatic dilation in the lung and pleura are additional features, likely related to pulmonary capillary hypertension and consequent chronically increased hydrostatic movement of fluid from the capillaries into the interstitium.

The incidence and prevalence of PVOD are unknown, owing at least in part to frequent misdiagnosis as IPAH. Thirteen percent of cases in the NIH registry had histologic changes of PVOD.[37] In a pooling of IPAH patient series in which cases meeting criteria for a diagnosis of PVOD were reported, an incidence of 0.1 to 0.2 cases per million persons in the general population has been estimated.[219] Prospective studies have not been performed, however, and this figure likely underestimates the true incidence of PVOD, as some cases are likely misclassified as either interstitial lung disease or heart failure because of similarities in radiographic appearance.[338] There is no apparent predilection for women (as is seen in IPAH), and patients have been diagnosed from infancy to the seventh decade of life.[339]

Although risk factors for sporadic PVOD are not well known, a genetic defect in familial cases of PVOD has been identified.[340] EIF2AK4 mutations were linked to 13 of 13 families with PVOD. In addition, this defect was also seen in 5 of 20 sporadic cases of PVOD. Case reports of PVOD complicating treatment of cancer with various chemotherapeutic agents (notably mitomycin, bleomycin, carmustine, and gemcitabine) or following bone marrow transplantation suggest that toxic exposures might elicit pathologic vascular responses.[341–353] Other case reports have noted the development of PVOD in association with various thrombophilic states, autoimmune disorders, or following bacterial or viral infection, including HIV.[354–361]

Patients with PVOD usually present with dyspnea and fatigue; symptoms less typical of other forms of PAH such as cough, orthopnea, and hemoptysis also have been observed.[199,362–366] The presence of basilar inspiratory crackles on physical examination favors a diagnosis of PVOD over other forms of PAH although these are clearly nonspecific. Decreased basilar breath sounds might suggest the presence of pleural effusions, which tend to occur more commonly in PVOD.[367,368]

The diagnosis of PVOD is suggested by the triad of pulmonary hypertension, radiographic evidence of pulmonary edema, and a normal PAWP. Unfortunately, all three are not universally present in cases of PVOD and the diagnosis frequently is delayed because of confusing findings during evaluation. As an example, "high probability" findings on ventilation–perfusion scanning, a frequent finding in PVOD due to heterogeneously impaired venous runoff, may lead to an erroneous diagnosis of CTEPH.[369] Findings on plain radiographs and CT scans in PVOD include enlargement of the central pulmonary arteries, peribronchial cuffing, Kerley B lines, interstitial infiltrates, and pleural effusions that in other circumstances might suggest left heart failure.[199,370]

In the appropriately placed pulmonary artery catheter with its balloon inflated, there is a static column of blood from the catheter tip to the left atrium and the pressure transduced is reflective of left heart chamber filling pressures (which should be normal in patients with PVOD).[371,372] Obtaining an adequate tracing, however, can be difficult and may require positioning the catheter in multiple areas. Of note, there may be a marked rise in measured pressure and a subsequent slow decline back to normal when saline is flushed through the wedged catheter; this is presumed due to impaired run-off of fluid through the restricted pulmonary venous vessels.

The definitive antemortem diagnosis of PVOD often requires surgical biopsy but this frequently is avoided due to increased operative and anesthetic risk in the setting of severe pulmonary hypertension, particularly given the questionable impact on therapy that establishing the diagnosis produces. However, establishing a diagnosis does provide prognostic information to the patient, may influence the urgency of evaluation for lung transplantation, and may be helpful in avoiding needless and possibly harmful therapies.

The features atypical of other forms of PAH (e.g., radiographic abnormalities "normally" consistent with left heart failure) should prompt caution when considering acute vasodilator testing.[199,370] Acute pulmonary edema, at times life-threatening, has been precipitated by the administration of vasodilators to patients with PVOD.

There are no established therapies for PVOD. Controlled studies have not been performed and only anecdotal reports are available. These describe both positive and negative responses to various agents. Some patients have experienced benefit while others have died with the use of calcium channel antagonists, intravenous epoprostenol, or other advanced therapies.[199,373–378] Glucocorticoids and other immunosuppressive agents have been attempted but experience has been anecdotal, with mixed results, and their use is not generally recommended except in rare cases where a concomitant inflammatory condition exists.[338,379,380] As in other forms of PAH, diuretics and supplemental oxygen should be employed as indicated. Lung transplantation is the only therapeutic option for many patients. The prognosis of patients with PVOD is poor, with most dying within 2 years of diagnosis.

■ Pulmonary Capillary Hemangiomatosis

Pulmonary capillary hemangiomatosis is another rare form of PAH with predominant involvement of the pulmonary veins. In many cases, its features overlap with PVOD, leading many to consider the two entities a single process. Pathologically, the findings are those of "pulmonary microvasculopathy" marked by angioproliferative capillary lesions that appear to invade the pulmonary vessels, interstitium, and in some cases the airways.[381,382] The etiology is unknown. Descriptive studies have reported the presence of vascular growth factors as well as markers of altered endothelial cell proliferation; altered expression of nitric oxide synthase also has been noted.[383–385] Mutations in EIF2AK4 have also been observed in both familial and sporadic cases of PCH—further supporting the overlap with PVOD.[386]

Epidemiologic features of the disease are not well understood, as only scattered case reports are available for evaluation. Pulmonary capillary hemangiomatosis may present with dyspnea and episodes of hemoptysis, and cases both with and without associated pulmonary hypertension have been reported. The radiographic findings are described as diffuse bilateral reticulonodular infiltrates, often associated with enlargement of the central pulmonary arteries.[387,388] The prognosis is poor, with most cases reported as fatal, often rapidly. Attempts at treatment with intravenous epoprostenol have resulted in pulmonary edema.[389–391] Successful treatment of several patients has been described with interferon α; another patient with superimposed endotheliomatosis was stabilized with doxycycline.[392,393] Urgent evaluation for lung transplantation is recommended.

■ Schistosomiasis

Schistosomiasis, also referred to as bilharzia or snail fever, is caused by infection with any of several species of the trematode flatworm fluke *Schistosoma.* Typically, humans contract schistosomiasis by contact with shallow water that contains snails that are intermediate hosts of the *Schistosoma* pathogen. Cercariae, the life-cycle stage released from infected snails, may penetrate human skin and after a conformational change to become schistosomulae, reach the lungs.[394] Lung involvement tends to develop after extensive chronic liver involvement, and there is debate about the relative contributions of POPH, periovular granulomas in the lungs, and host immunologic changes in producing PAH-like pathologic changes in up to 9% of patients.[395] It is estimated that up to 300 million individuals worldwide have schistosomiasis, and as such it is likely to be one of the most numerically important causes of PAH. Patients generally present clinically with dyspnea on exertion and other features similar to PAH due to other causes. Diagnosis requires documentation of PAH via hemodynamic assessments along with clinical and serologic evidence of *Schistosoma* infection.

Much remains unknown regarding the prognosis and optimal approach to therapy. One series of 54 patients in Brazil suggested a more benign course than IPAH patients at the same institution.[396] Treatment with prostenoids, endothelin antagonists, and phosphodiesterase 5 inhibitors appears efficacious in improving hemodynamics and 6-min walk distance, although large randomized trials are lacking.[397] The antischistosomal agent praziquantel can reverse pulmonary hypertension and vascular remodeling in murine schistosomiasis although its efficacy in human disease is not documented.[398]

THERAPY FOR PULMONARY ARTERIAL HYPERTENSION

The many facets and challenges in treating pulmonary arterial hypertension are presented below.

■ A Cautionary Note: Non-PAH Forms of Pulmonary Hypertension

Therapy must be driven by an appropriately established diagnosis.[399] As noted previously, PAH is but one form of pulmonary hypertension and overall less common than pulmonary hypertension due to parenchymal lung or left heart disorders. Appropriate therapy for pulmonary hypertension due to left heart disease or parenchymal lung disease centers on optimal management of the underlying left heart disorder or lung disease, respectively. Far too often focus on the presence of pulmonary hypertension distracts clinicians' attention from the underlying cause. This not only leads to inappropriate use of drugs that are of established benefit only among patients with PAH, but may be accompanied by a failure to pursue appropriate therapies more likely to relieve a patient's symptoms (such as appropriate fluid management for left heart failure, interventions for coronary artery disease, correction of a mitral or aortic valvular dysfunction, bronchodilators and other inhaled medications for obstructive lung disease, or control of systemic hypertension). Other times, when underlying lung or left heart disorders have been maximally treated and symptoms remain, frustrated clinicians and patients may be driven to "blame" persistent problems on the presence of pulmonary hypertension. They may try drugs approved for treatment of PAH, reasoning that "there is nothing else to do," or that "it couldn't hurt." Unfortunately, such an approach is currently ill-informed and potentially harmful.

The use of drugs approved for treatment of PAH in patients with other forms of pulmonary hypertension has not been found to be beneficial and is associated with known harms ranging from well-established side effects to worsening survival.[400] For example, randomized trials of patients with decreased left ventricular systolic function have raised concerns for worsened heart failure with the use of endothelin receptor antagonists, and have resulted in an increased risk for death with epoprostenol infusion.[401,402] Another randomized trial of patients with COPD and echocardiographic evidence of pulmonary hypertension found use of bosentan worsened hypoxemia and quality of life, and failed to improve exercise capacity.[403] Despite suggestion of improved exercise capacity among patients with left heart dysfunction and pulmonary hypertension treated with sildenafil in a preliminary study, a larger randomized trial found no improvement, and there were more adverse events among the participants who received sildenafil.[404,405] Sildenafil was also associated with more adverse events compared with placebo in the SIOVAC study of patients with pulmonary hypertension after corrected valvular heart disease.[406] In the RISE-IIP study randomizing patients with idiopathic interstitial pneumonia to riociguat versus placebo, there were more deaths observed in the treatment arm, which prompted early termination of the study.[407] Accordingly, the misapplication of PAH targeted therapies is not just costly or ineffective, but can also be associated with serious harm including premature death.

■ General Management

A variety of pharmacologic and nonpharmacologic interventions are used in treatment of pulmonary arterial hypertension. PAH-specific pharmacotherapy is discussed in a separate section, below.

Exercise and the Avoidance of Deconditioning

Regardless of the cause, patients with pulmonary hypertension and cor pulmonale should be encouraged to maintain as active a lifestyle as possible. Recommendations that the patient minimize exertion for fear of further raising pulmonary pressures generally result only in deconditioning of the muscles and an increase in fatigue and breathlessness when an activity is attempted. Regular, steady aerobic exercise should be encouraged and is often best initiated under guidance of a pulmonary or cardiac rehabilitation program. Indeed, randomized trials of exercise rehabilitation in patients with PAH or CTEPH have demonstrated not only the safety of exercise in these patients, but improvements in exercise capacity (e.g., 6-min walk distance) greater than that observed in randomized clinical trials of currently available pharmacologic treatments for PAH. Clinically significant improvements in exercise capacity, as well as health-related quality of life, occurred in both an intensive exercise regimen beginning with inpatient therapy, as well as a 10-week outpatient program of treadmill walking similar in intensity to that commonly used in pulmonary and cardiac rehabilitation programs.[408,409] In addition to improving strength and endurance, the benefits of a supervised rehabilitation program may include a decrease in the fear many patients with dyspnea experience when initiating exercise programs. Many rehabilitation programs teach techniques to cope with dyspnea when it occurs, allowing exercise to continue. Importantly, activities that cause patients to experience lightheadedness or syncope should be avoided, including hot showers or baths and bending over to lift heavy objects.

Oxygen Therapy

Although controlled studies analogous to those performed in the treatment of COPD have not been conducted,[410] it is recommended that patients with pulmonary hypertension avoid acute hypoxia, as hypoxic pulmonary vasoconstriction will add to the burden on the right ventricle. Oxygen relieves hypoxic pulmonary vasoconstriction, thus decreasing vascular resistance and improving CO. It also lessens renal vasoconstriction, improving urinary sodium excretion, and alleviates tissue hypoxia by improving oxygen delivery. Measurements of arterial oxyhemoglobin saturation should be performed at rest, with exertion, and with sleep. Levels of arterial oxygen saturation below 90% should prompt supplemental oxygen. Maintenance of adequate oxygen saturation may be difficult in patients with severe pulmonary hypertension in whom a patent foramen ovale allows right-to-left shunting.

Air travel is a particular concern because of the threat of hypoxic pulmonary vasoconstriction. Measurements made during commercial airline flights lasting a mean of 3.6 h in a series of patients with PAH or CTEPH found that oxyhemoglobin desaturation below 85% occurred in 26% of participants, at a mean cabin pressure of 1971 ± 73 m (6467 ± 240 ft) with the lowest occurring at 1829 m (6000 ft).[411] More than one-third of patients developed symptoms during flight. Although more definitive studies have not been performed, it seems prudent to evaluate pulmonary hypertension patients who plan air travel that will last more than a few hours for in-flight oxygen use, particularly among patients with prior need of supplemental oxygen (including with sleep only). Many pulmonary function laboratories can simulate conditions of high altitude with an inspired oxygen concentration of 15% to determine whether the patient requires supplemental oxygen to maintain adequate oxyhemoglobin saturation. Patients should contact airlines in advance of travel as requirements differ, as do costs (which regrettably may not be covered by insurance). An attractive alternative to stored oxygen systems are portable concentrators, which most airlines will permit patients to carry on board without special arrangements.

Immunizations

Immunizations against influenza and pneumococcal pneumonia are important preventive measures in all patients with pulmonary hypertension and cor pulmonale. Influenza vaccination should occur annually, and the 23-valent polysaccharide pneumococcal vaccine and the 13-valent pneumococcal protein-conjugate vaccine should be administered per recommended protocols.

Fluid Management and Diuretics

Careful attention to avoid fluid overload is central to the management of right heart dysfunction of any cause. Patients must be educated regarding appropriate dietary habits and to restrict sodium intake to minimize fluid retention and the development of right heart failure. Patients should weigh themselves daily so that any trend toward fluid retention can be reversed before progressive right ventricular overload results in failure that may then be more difficult to reverse and require inpatient treatment.

Management of right heart failure relies heavily on diuretic therapy. Spironolactone is often used to manage mild fluid retention. It may also have beneficial effects in heart failure by modulating neurohormones. Loop diuretics are often required to prevent more significant fluid retention and right heart failure. Indeed, high doses and combinations of diuretics are often required to maintain appropriate fluid balance but must be used cautiously to avoid electrolyte imbalances and volume depletion.

Digitalis

It is unsettled whether cardiac glycosides should play a role in treating right heart failure. In a series of 17 patients with PAH and right ventricular failure, the intravenous administration of 1 mg of digoxin resulted in a modest increase in CO after 2 h[412] but longer-term data are lacking. Approximately 25% of patients in the REVEAL registry were using digoxin,[194] but many physicians avoid use of this agent even when right-sided heart failure is evident on account of a lack of sufficient evidence regarding its use in PAH and the potential for toxicity.

Anticoagulation

In the absence of contraindications, anticoagulation was previously recommended for patients with significant IPAH.[194,200] This is reasoned to be of benefit on the basis of autopsy studies revealing in situ thrombosis in both venous and arterial vessels without evidence of an embolic source in a significant proportion of patients with PAH.[44–46] Anticoagulation is also justified on the basis of the increased risk of venous thromboembolic disease in patients with severe heart failure and immobility, and based on their expected poor tolerance of embolic events. The efficacy of anticoagulant therapy in patients with PAH has never been studied in randomized controlled trials. Recent large registries, however, have shed more light—but also provided some conflicting results regarding the role of anticoagulation and PAH. In the European COMPERA registry of 1283 consecutive PAH patients, there was a survival benefit observed in IPAH treated with anticoagulation compared with those not on anticoagulation therapy.[413] They observed no benefit of anticoagulation with other forms of PAH in this registry. In contrast, the REVEAL registry in the United States compared PAH patients initiated on warfarin and matched those cases with similar PAH patients not on warfarin therapy.[414] They observed no survival difference among the IPAH patients treated with warfarin with matched controls. Furthermore, patients with scleroderma-associated PAH treated with warfarin had worse survival than the matched controls not on warfarin therapy. Accordingly, firm guidance regarding the use of oral anticoagulation therapy in PAH is lacking and the practice is shifting with time. The evidence remains weak but favors the use in IPAH. A role for newer, non-warfarin oral anticoagulants (e.g., rivaroxaban, dabigatran, apixaban) has not been defined in patients with PAH.

Contraception and Pregnancy

Pregnancy in women with IPAH is associated with a high maternal mortality, on the order of 30% to 50%.[415–417] Expert consensus is that pregnancy should be avoided, and early termination recommended on account of the high maternal mortality.[194,200] Effective contraception should be ensured; if hormonal contraception is chosen, anticoagulation may be advisable to reduce the risk of venous thromboembolism. Although the successful management of pregnancies in PAH has been reported,[418] single and multicenter series continue to report high rates of maternal death despite the use of aggressive treatments including intravenous prostenoids.[419–421]

Other Considerations

Patients should be queried about the concomitant use of medications and herbs. Warfarin is particularly apt to be associated with drug–drug interactions. The use of vasoconstrictor or serotonergic medications for unrelated illnesses, such as migraine, also should be undertaken cautiously. Surgical procedures may entail considerable operative and postoperative risk in patients with hemodynamic compromise from PAH. The vulnerability of patients with severe PAH to vasovagal events has to be kept in mind. An attack can be precipitated by pain, nausea, vomiting, or straining (Fig. 72-13). The induction of anesthesia and intubation may be a particularly troublesome time. The combination of bradycardia and systemic vasodilation can lead to a precipitous drop in systemic blood pressure. Atropine or a similar agent should be kept at hand during invasive procedures.

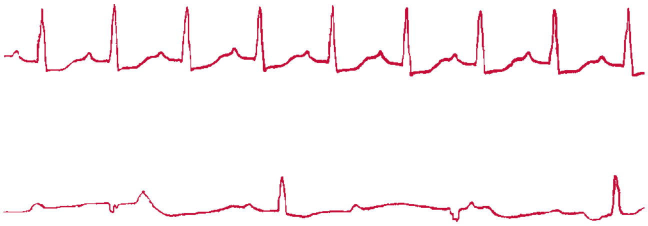

Figure 72-13 Idiopathic pulmonary arterial hypertension. Bradycardia and prolongation of atrioventricular conduction progressed to atrioventricular dissociation while patient was on bedpan. Associated with syncope.

PAH-TARGETED PHARMACOTHERAPY

Treatment of PAH aims to improve the hemodynamic derangements and right heart dysfunction caused by pulmonary hypertension. Although commonly referred to as pulmonary vasodilators, the approved PAH targeted agents also importantly have antiproliferative properties that may ameliorate some of the detrimental vascular changes seen in untreated disease.[422] Remarkable progress in the treatment of PAH has resulted in the availability of multiple therapies affording a significantly improved outlook and long-term survivors. No currently available medical treatment, however, is curative and despite durable clinical improvement in many patients, histopathologic changes of vasculopathy often remain.[423] Lung transplantation remains an option when patients continue to progress despite optimal medical management.

The majority of PAH subjects studied in controlled clinical trials have been patients with idiopathic or heritable PAH, and PAH associated with connective tissue diseases. Since most of these early studies compared a single agent to placebo, our knowledge regarding the relative efficacy of available agents is limited by the lack of head-to-head comparisons. In addition, patients treated in earlier studies were generally sicker than those treated in more recent PAH studies, which have allowed for stable background PAH therapy prior to enrollment.

In the absence of head-to-head comparison trials, care must be taken in comparing and applying the results of clinical trials of different pharmacologic agents. Most clinical trials have enrolled patients and assessed response at least in part on the basis of a WHO modification of the New York Heart Association functional assessment of patients with heart failure (Table 72-4), and there appears to be substantial variability in even expert clinicians' judgments of a given patient's functional class.[424,425] The early PAH studies most commonly used an exercise surrogate endpoint of 6-min walk test. With few exceptions, improvements in this parameter have been the basis for most of the PAH drugs approved by the FDA. The minimal clinically meaningful change in 6-min walk distance (6MWD) in patients with PAH has been estimated to be between 33 and 42 m.[426,427] These estimates, however, have been made using data from trials of predominantly treatment-naïve patients and may not be applicable when additional therapies are added.[428,429]

There has not been a new targeted pathway for PAH therapy since the FDA approval of sildenafil for this indication in 2005. The subsequent drug developments were either alternative analogues or novel mechanisms of action within the three established PAH treatment pathways. Rather than simply replicating earlier study results, these newer agents had to demonstrate safety and efficacy on top of background therapy(-ies) and/or show improvements in clinical outcomes beyond 6MWD.[430] Furthermore, rather than short 12- or 16-week clinical trials comparing walk distances as in many of the early PAH drug registration trials, more recent trials have shifted to morbidity and mortality endpoints requiring larger sample size and longer study duration. In such trials, 6MWD has been incorporated into a component of a composite endpoint, rather than serving as the primary endpoint. This evolution in PAH trial design and study conduct has also influenced our treatment expectations from short-term specific parametric gains (such as exercise tolerance based on the surrogate of 6MWD) to long-term global patient benefit (e.g., fewer clinical events such as disease progression or hospitalization related to PAH).

In general, the choice of initial therapy depends upon an assessment of disease severity and the patient's prognosis and risk for further deterioration. Multiple PAH risk assessment tools have been proposed to guide such clinical decisions and offer prognostic information.[431–433] This judgment involves an assessment of a combination of variables, including right heart assessment via hemodynamics and echocardiographic findings, exercise capacity, functional classification, and recent clinical stability or deterioration (Table 72-9).[399] The REVEAL 2.0 risk score is another powerful risk assessment tool incorporating additional patient factors such as age, vital signs, renal function, and hospitalizations within the previous 6 months (Fig. 72-11).[433]

Regardless of the choice of risk assessment tool, patients deemed to be at low or intermediate risk are generally treated with oral agents, whereas high-risk patients are treated with a regimen including parenteral prostanoid therapy.[434] No single variable determines the choice of therapy. For example, a WHO functional class III patient without rapid recent clinical change and a cardiac index above 2.5 L/min/m^2 might be appropriately treated initially with oral therapy. A WHO functional class III patient who is either rapidly declining clinically or who has more severely depressed cardiac index due to right heart dysfunction, however, might be more appropriately managed initially with intravenous prostanoid therapy. Personal preferences often influence a patient's willingness to undertake intravenous therapy. In addition, psychosocial issues, cognitive abilities, and other determinants of patient adherence may make certain therapies unsafe even if otherwise medically indicated.[435]

Although there are not well-established guidelines to follow up individual PAH patients after initiation of therapy, there are some general principles shared by expert PH centers. In addition to the clinical and functional class assessment, varying combinations of 6MWD, echocardiogram, and serum biomarkers are examined as part of a global PAH risk assessment. Right heart catheterization is also valuable depending on the clinical scenario in order to provide additional objective information and help guide further treatment. Reassessment frequency typically depends on the relative stability and risk profile of the individual PAH patient. The optimal strategy of interval testing to improve patient outcomes has not been clearly determined, nor has the relative cost-effectiveness of different approaches.

■ Calcium Channel Blockers

Calcium channel blockers (CCBs) were available prior to the three PAH targeted pathways discussed below.[436] Although not approved for PAH treatment, CCBs are still have a therapeutic role in the rare subset of PAH patients with demonstrated acute pulmonary vasoreactivity.[6] CCBs diminish vascular tone by preventing an increase in cytosolic calcium concentration through inhibition of both the influx of extracellular calcium and the release of calcium from intracellular stores. The long-term prognosis is good for some PAH patients who respond acutely to the administration of short-acting pulmonary vasodilators such as inhaled nitric oxide, intravenous adenosine, or intravenous epoprostenol, and are then treated subsequently with CCB therapy. In one study, the survival rate of acutely vasoreactive patients treated chronically with oral calcium antagonists was maintained at 94% when measured at 1, 3, and 5 years.[436] Unfortunately, relatively few patients demonstrate acute vasoreactivity (∼10% by recent estimates), and of these only about one-half experiences a sustained clinical response.[437]

Oral CCBs should not be used as vasodilator therapy in the absence of documented acute vasoreactivity. The current definition of a positive acute vasoreactive response is a decrease in mean pulmonary arterial pressure (mPAP) by ≥10 mm Hg to absolute mPAP

TABLE 72-9 PAH Risk Assessment: 2015 ESC/ERS Guidelines

Determinants of Prognosis[3] (Estimated 1-Year Mortality)	Low Risk <5%	Intermediate Risk 5%–10%	High Risk >10%
Clinical signs of right heart failure	Absent	Absent	Present
Progression of symptoms	No	Slow	Rapid
Syncope	No	Occasional syncope[13]	Repeated syncope
WHO functional class	I, II	III	IV
6MWD	>440 m	165–440 m	<165 m
Cardiopulmonary exercise testing	Peak$\dot{V}O_2$ >15 mL/min/kg (>65% pred.) VE/VCO, slope <36	Peak$\dot{V}O_2$ 11–15 mL/min/kg (35%–65% pred.) VE/VCO, slope 36–44.9	Peak$\dot{V}O_2$ <11 mL/min/kg (<35% pred.) VE/VCO, slope >45
NT-proBNP plasma levels	BNP <50 ng/L NT-proBNP <300 ng/L	BNP 50–300 ng/L NT-proBNP 300–1400 ng/L	BNP >300 ng/L NT-proBNP >1400 ng/L
Imaging (echocardiography, CMR imaging)	RA area <18 cm^2 No pericardial effusion	RA area 18–26 cm^2 No or minimal pericardial effusion	RA area >26 cm^2 Pericardial effusion
Hemodynamics	RAP <8 mm Hg CI >2.5 L/min/m^2 SvO >65%	RAP 8–14 mm Hg CI 2.0–2.4 L/min/m^2 SvO 60%–65%	RAP >14 mm Hg Ci <2.0 L/min/m^2 SvO <60%

Eur Heart J. 2016;37(1):67–119.

≤40 mm Hg, with an unchanged or increase in cardiac output.[6] Those failing to demonstrate acute vasoreactivity not only fail to benefit from CCB therapy, but are also prone to adverse side effects including systemic hypotension, decreased cardiac output because of negative inotropic effects, arrhythmias, salt and water retention, syncope, and death. Acute vasodilator testing as described earlier is therefore required to determine whether a clinical trial of CCB therapy is appropriate. Patients treated with CCBs must be monitored for the development of side effects including systemic hypotension, peripheral edema, and gingival hypertrophy, as well as for evidence of continued benefit.

■ Prostacyclin Pathway Therapies

The prostacyclin analogue epoprostenol was the first FDA-approved therapy for the treatment of PAH.[438] To this day, intravenous prostacyclin therapy remains invaluable for the treatment of PAH and represents the most potent of PAH therapies. Prostacyclin is a powerful vasodilator (both pulmonary and systemic) as well as an inhibitor of smooth muscle proliferation and platelet aggregation. It is a product of arachidonic acid metabolism and acts, at least in part, by stimulating the intracellular production of cAMP. Its major source is the vascular endothelial cell and deficiencies are noted in patients with PAH, although it is unclear whether these lower levels represent a cause or an effect of PAH. Several synthetic prostacyclin analogues are available for the long-term treatment of PAH, including formulations administered by continuous intravenous infusion (epoprostenol and treprostinil), subcutaneous infusion (treprostinil), inhalation (treprostinil and iloprost), or oral therapy (treprostinil). In addition, selexipag is an oral specific IP receptor agonist that selectively targets the prostacyclin receptor.

Parenteral prostanoid therapies require a capable and compliant patient for safe administration, preferably in conjunction with a strong social support system at home. Intensive patient and family education is required for safe initiation of therapy. Particularly for intravenous prostanoid initiation, the patient is typically hospitalized until appropriate understanding and proficiency in self-care is demonstrated. While appropriate expertise in the management of PAH is required for nonparenteral treatments, parenteral prostanoid therapy in particular requires the intensive support of a dedicated team of nurses and physicians at a program with sufficient expertise, typically with the additional assistance of nurses from specialty pharmacies.[439]

Intravenous Prostanoid Therapy (Epoprostenol, Iloprost, and Treprostinil)

The first prostanoid therapy shown in randomized clinical trials to be beneficial in the treatment of PAH was epoprostenol.[438] Because of its short half-life in the order of minutes, it requires continuous intravenous infusion. In an initial study, 81 patients with IPAH were randomized to receive epoprostenol infusion or treatment considered “standard” at the time (oral vasodilators, diuretics, cardiac glycosides, and anticoagulants). After 12 weeks of treatment, hemodynamic values were improved in the epoprostenol group (e.g., a 21% decrease in PVR compared with an increase in control patients), as was the 6MWD (increased by 31 m compared with a decrease of 29 m). None of the patients treated with epoprostenol died during the study; a 20% mortality by 12 weeks was observed with conventional therapy. Intravenous epoprostenol for IPAH was approved by the FDA in 1995 and remains to date one of the most potent and effective PAH therapies.

Additional reports have confirmed and extended these observations. Although originally conceived as a “bridge” to lung transplantation in patients with severe PAH, the long-term use of epoprostenol and other treatments was followed by a decrease in the demand for lung transplantation for this indication.[440] In a cohort of 162 IPAH patients treated with intravenous epoprostenol in the United States, the observed 1- and 3-year survival rates were 88% and 62%, compared with rates of 59% and 35% predicted by the NIH registry equation.[237] Remarkably similar results were observed in a cohort in France of 178 epoprostenol-treated patients with IPAH at 1 and 3 years.[236] In each case, survival was improved over that predicted by the NIH registry equation.

Epoprostenol infusion therapy has also been used in other forms of PAH. A randomized multicenter trial in patients with systemic sclerosis–associated PAH (without significant interstitial lung disease) showed improvements in both hemodynamics and exercise capacity.[441] Favorable results of epoprostenol treatment have also been reported in uncontrolled series of patients with systemic lupus erythematosis,[442] congenital left-to-right shunts,[443] anorectic agent use,[319] HIV, portopulmonary hypertension (PoPH),[299] and inoperable CTEPH.[444] Epoprostenol has been used successfully in some patients with PVOD. The use of epoprostenol in patients with PVOD must be approached with extreme caution, however, as its use in patients with impeded venous blood flow has precipitated pulmonary edema in some individuals.[219] Isolated attempts at treating patients with pulmonary capillary hemangiomatosis (also characterized by predominant involvement of the pulmonary veins) have resulted in death.[393] In one randomized trial of patients with left ventricular dysfunction (FIRST study), the use of epoprostenol was associated with a trend toward increased mortality, resulting in early termination of the study.[401] This study remains an important reminder that PAH-targeted therapy applied in other PH populations may be harmful.

Treprostinil is an alternative prostanoid analogue for intravenous therapy that has a longer half-life (4 h) and greater stability at room temperature. Treprostinil appears to have acute hemodynamic effects similar to those of epoprostenol.[445] In one uncontrolled, 12-week, open-label study of 16 PAH cases (8 with IPAH and 6 and 2 associated with connective tissue disease and congenital heart disease, respectively) intravenous treprostinil infusion resulted in an 82-m improvement in 6MWD as well as improvements in hemodynamic values.[446] In a subsequent 12-week, placebo-controlled, randomized trial of 44 PAH patients, continuously infused treprostinil resulted in an 83-m placebo-corrected increase in 6MWD and improvements in functional class.[447] Importantly, this randomized study involved the placement of central venous catheters for placebo infusions (associated with harm, including one death). This has raised ethical concerns and questions regarding optimal conduct of future investigations.[448,449]

Intravenously administered iloprost, another prostanoid, is available in some European countries, but not in the United States. In uncontrolled trials it has been used in patients with IPAH, connective tissue disease–associated PAH, and CTEPH.[450–452] The acute hemodynamic effects are similar to those of epoprostenol, but no controlled trials of its efficacy are available. In a retrospective analysis of 50 patients with PAH treated at multiple centers in Germany with intravenous iloprost following insufficient or deteriorating clinical status after the use of oral therapy with endothelin receptor antagonists or phosphodiesterase type 5 inhibitors, only ∼25% had an improved functional class at 3 months, and more than 50% of patients died or required lung transplantation within 1 year.[453]

Epoprostenol therapy is initiated at 2 ng/kg/min and gradually increased in 0.5- to 1-ng/kg/min increments at intervals dictated by patient side effects and response. Treprostinil is initiated at 1.25 ng/kg/min and similarly increased as dictated by clinical response, typically in increments of 1.25 ng/kg/min. Induced metabolism mandates a need for continuous increases in dosage to maintain improvements in symptoms. Increases are usually required at more frequent intervals initially to relieve symptoms due to PAH (e.g., dyspnea and lightheadedness), although many patients will reach a more stable dosing with less frequently required increases after several weeks to months. Such titration must be closely monitored for prostanoid side effects (nausea, tachycardia, diarrhea, masticatory jaw pain).[439] Patients lacking an acute vasodilator response (e.g., to inhaled nitric oxide or infused epoprostenol) have shown improved hemodynamics and exercise capacity after sustained treatment, suggesting that the beneficial effects are not mediated merely through acute vasodilation but rather by beneficial vascular remodelling.

Intravenous treatment with epoprostenol or treprostinil requires a tunnelled central venous catheter and thus is associated with a significant risk of bacterial infection. In an evaluation of 1146 patients who received intravenous prostanoid therapy during more than 3 years of the multicenter observational U.S.-based REVEAL cohort, an approximate threefold increase in bloodstream infections of any type and more than a sixfold increase in those due to gram-negative organisms was observed among patients receiving intravenous treprostinil compared with intravenous epoprostenol.[454] A retrospective study by the U.S. Centers for Disease Control of data from seven PAH treatment centers also concluded that rates of bloodstream infection were higher with continuous intravenous infusions of treprostinil than epoprostenol. The higher rate of infection did not appear to be due to intrinsic drug contamination[455] but may have been related to the neutral pH of the treprostinil diluent, as substitution with the basic pH epoprostenol diluent appeared to eliminate the increase in infection rates with treprostinil at one institution.[456]

Prostanoid infusion requires the use of a battery-powered portable infusion pump that must be carried at all times. A back-up medication cassette and pump must also be immediately available, as an interruption of only minutes can result in hemodynamic compromise. In theory, the risk with interrupted treprostinil infusion is somewhat lower on account of its longer half-life. The originally available formulation of epoprostenol is unstable at room temperature and must be mixed daily and kept cool with ice packs. Like treprostinil, a subsequently approved formulation of epoprostenol has greater stability at room temperature and does not require continuous cooling with ice packs.[457] Experience suggests that a higher dosage of treprostinil is required than epoprostenol to maintain an improvement in symptoms.[458] Further observation is required to establish whether survival is similarly improved with treprostinil as with epoprostenol. Experience and established duration of benefit is greatest with epoprostenol infusion, and it remains an important treatment for severe PAH and a benchmark against which other therapies are often compared.

Subcutaneous Prostanoid Therapy

Treprostinil was first approved for subcutaneous (SC) administration prior to intravenous use. In a large, randomized, double-blind, placebo-controlled trial of 470 patients with IPAH or PAH associated with congenital heart or connective tissue disease, SC treprostinil resulted in improvements in hemodynamic parameters and a modest improvement in 6MWD of 16 m at 12 weeks.[459] In an open-label extension study of participants previously enrolled in the randomized trial, together with de novo patients, survival up to 4 years was evaluated in 332 IPAH patient for whom baseline hemodynamic measurements were available. Observed survival was 91% and 72% at 1 and 4 years, respectively, compared with survival rates of 69% and 38% at 1 and 4 years predicted by the NIH registry equation.[460]

The major advantage of SC treprostinil is avoidance of an intravenous catheter and the associated risk of life-threatening bacteremia. The major drawback of SC treprostinil has been a significant incidence of troublesome infusion-site pain. This occurred in 85% of patients in the pivotal clinical trial and led to discontinuation in 8%.[459] Of 860 total patients in the previously noted open-label study, 196 (23%) discontinued SC therapy due to infusion-site pain or reactions.[460] Management strategies to reduce the occurrence and severity of pain have been reported, including initial "dry" catheter insertions with delayed infusion of medication, less frequent site rotations, and the application of topical analgesics and anti-inflammatory agents.[461] For those with severe pain refractory to these measures, narcotic analgesics may be required. Another relative disadvantage is a slower rate of dosage titration compared with intravenous therapy, making it less attractive for severely ill patients in need of a rapid response. In select patients, however, SC treprostinil has proved to be effective therapy and has allowed for avoidance of the risks and inconveniences associated with intravenous therapy.

Inhalational Prostanoid Therapy (Iloprost and Treprostinil)

Inhaled prostanoid therapies have been developed in the hopes of avoiding the need for an invasive delivery system. Iloprost is an inhaled prostacyclin analogue. A pivotal 12-week, randomized, placebo-controlled trial of 203 patients demonstrated improvement in composite primary endpoint including a placebo-corrected improvement of 36 m in 6MWD.[462] Most of the patients studied had IPAH; the remainder had PAH associated with anorectic agent or connective tissue disease, or had inoperable CTEPH. Functional class and quality-of-life measures also improved in association with treatment. Hemodynamic variables were improved at 12 weeks when measured following a dose of iloprost, although pre-inhalation values were unchanged. As in other trials of PAH therapies, hemodynamic variables were worse compared with baseline following 12 weeks of placebo. Following another 3-month placebo-controlled study, 52 patients received open-label iloprost therapy. At 2 years, 36 (69%) remained on iloprost while treatment was discontinued in 16 patients due to death, lack of efficacy, and adverse events in 2, 6, and 6 patients, respectively. The study included patients with PAH and non-PAH forms of disease. The 2-year event-free survival was 74% in the IPAH patients, compared with a predicted survival of 63% according to the NIH formula.[463]

Treprostinil is also available for inhalational therapy. A 12-week, double-blind, placebo-controlled, randomized trial of 235 patients with PAH already receiving either endothelin receptor antagonists or phosphodiesterase type 5 inhibitor therapies demonstrated an overall 20-m improvement in post-inhalation 6MWD compared with baseline (14 m in pre-inhalational distance), as well as improved measures of quality of life. There was no difference in the time until clinical worsening.[464] An open-label extension of 206 patients from this trial found a median 18-m improvement over baseline 6MWD after 24 months.[465]

In addition to the lack of need for invasive administration equipment, inhaled prostanoid therapy is easier to initiate. However, frequent dosing is required (four times daily for treprostinil and between six and nine times per day for iloprost) and compliance may be a challenge. In addition, as the hemodynamic effects wane prior to each administration, whether patients receive the same benefit as with continuously infused prostanoid therapy is unclear.[466]

Iloprost inhalational therapy is initiated at a dosage of 2.5 μg and increased to 5 μg with the subsequent dose if tolerated. Treprostinil is started at 18 μg (three breaths) four times a day, with dose escalation suggested every 1 to 2 weeks to a maximum and target dose of 54 μg (nine breaths) four times daily. Inhaled prostanoids are each administered with drug-specific portable delivery devices. Prostanoid side effects are seen with inhalational therapy, including headache, nausea, diarrhea, flushing, and jaw discomfort. Systemic hypotension and syncope also may occur, although they have not been associated with further clinical deterioration in clinical trials.

Oral Prostanoid and Prostacyclin Receptor Therapy

An orally active prostacyclin analogue, beraprost, has been studied in two randomized placebo-controlled trials of patients with various forms of PAH and appears to result in a nonsustained improvement in exercise capacity. An initial trial of 130 patients demonstrated an improvement in 6MWD after 12 weeks of therapy, but in a subsequent study of 116 patients the effect was not sustained beyond 6 months.[467,468] Neither trial demonstrated significant hemodynamic improvement compared with placebo, and beraprost is currently approved only in several Asian countries. An oral formulation of treprostinil has been studied with mixed results. In the Freedom M (monotherapy) study, 349 patients not on any approved background PAH therapy were randomized to either oral treprostinil or placebo for 12 weeks.[469] The primary endpoint of 6MWD noted a treatment effect of 23.0 m in patients receiving oral treprostinil. The most common side effects were headache (69%), nausea (39%), diarrhea (37%), and jaw pain (25%). In the parallel Freedom C (combination) study, 310 PAH patients were randomized between oral treprostinil and placebo for 16 weeks.[470] Unlike the monotherapy study, patients in this combination study were receiving background PAH therapy with either endothelin receptor antagonist or phosphodiesterase type 5 inhibitor, or both therapies at the time of enrollment. There were no significant differences in the primary endpoint of 6MWD at 16 weeks, nor in any secondary endpoints. Similar to Freedom M, the common treatment-related side effects were headache (71%), diarrhea (55%), nausea (46%), flushing (35%), and jaw pain (25%). Oral treprostinil was approved by the FDA for PAH based on these trials. The subsequently completed Freedom V study reported benefits of oral treprostinil in reducing risk of clinical worsening when added to PAH background monotherapy (26% event rate in treated group vs. 36% in the placebo group; HR, 0.74; $p = 0.028$).[471] Unlike in the prior Freedom studies, oral treprostinil was administered three times daily instead of twice daily in attempt to improve tolerability. The reported side effects, however, were similar to the prior two studies.

IP Receptor Agonist

The most recently approved therapy to target the prostacyclin pathway is the novel IP receptor agonist selexipag. Selexipag is an orally administered nonprostanoid IP receptor agonist that has been studied in the largest PAH clinical trial to date.[472] The GRIPHON study was designed as a morbidity/mortality study. This event-driven study randomized 1156 PAH patients and allowed for stable background mono- or combination PAH therapies. The first event to morbidity and mortality occurred in 41.6% of the placebo group versus 27.0% in the selexipag-treated group (HR, 0.60; $p < 0.001$). Within the composite primary endpoint, difference was driven by reduction in disease progression and hospitalizations due to PAH. Treatment discontinuation rate during the study was 14.3% in the selexipag group versus 7.1% in the placebo group. The most common adverse events associated with selexipag therapy included headache (65.2%), diarrhea (42.4%), nausea (33.6%), and jaw pain (25.7%). Following the approval of selexipag for the treatment of PAH, the safety and feasibility of switching from inhaled prostanoid to selexipag was investigated.[473] Of 34 patients on inhaled treprostinil as part of their PAH treatment, 32 patients maintained the switch from inhaled treprostinil to oral selexipag by 16 weeks and 28 of those patients met all predefined criteria for sustained transition. Treatment satisfaction questionnaire noted improvements in convenience from baseline to 16 weeks for those maintaining selexipag therapy. However, this was a small, uncontrolled study with a relatively brief follow-up. The safety of transitioning from or to other inhaled/oral prostanoid analogues is unknown. The current consensus opinion is that oral selexipag should not be initiated as replacement for parenteral prostanoid therapy or in high-risk PAH patients in need of parenteral therapy.[474]

Endothelin Receptor Antagonists

Endothelin 1 (ET-1) is a member of the endothelin family of peptides secreted by endothelial cells that promotes vasoconstriction and the proliferation of vascular smooth muscle and endothelial cells. ET-1 is overexpressed in the vasculature of patients with various forms of PAH, and antagonists of its interaction with its receptors (ET_A and ET_B) have been developed for oral use. Two dual ET_A/ET_B and one relatively ET_A-selective antagonist are currently available.

Bosentan is a dual ET_A/ET_B antagonist that improves hemodynamics, exercise capacity, WHO functional class, and the time to clinical worsening (defined as death, PAH-related hospitalization, need for altered therapy, or lung transplantation).[90,475] In a double-blind, randomized, placebo-controlled trial of patients with IPAH and PAH associated with connective tissue disease (predominantly systemic sclerosis), bosentan improved the 6MWD by 44 m compared with placebo at 16 weeks. Exercise capacity improved in IPAH patients, while stabilization or a slowing in the rate of deterioration was observed in patients with systemic sclerosis. The beneficial effects of bosentan on exercise capacity and functional class persist at 1 year with open-label use.[476] In a double-blind, randomized, placebo-controlled trial of PAH patients with less severe symptoms (WHO functional class II), bosentan treatment for 6 months improved hemodynamics and delayed clinical worsening compared with placebo.[477] However, there was no significant difference in exercise capacity as measured by 6MWD; both groups at baseline had 6MWD greater than 430 m. Survival of IPAH patients treated with bosentan in these trials and their open-label extensions was 96% at 1 year and 89% at 2 years, compared with “expected” survival of 69% and 57%, respectively, as predicted by the NIH registry equation.[92]

In a 16-week randomized controlled trial of patients with Eisenmenger syndrome that was primarily examining safety, bosentan use was associated with improved hemodynamics and exercise capacity, with persistent effects seen during a 24-week open-label extension.[478,479] Nonrandomized reports have suggested a benefit of bosentan in other specific PAH populations. A prospective open-label study of 16 patients with PAH associated with HIV infection reported improved hemodynamics, exercise capacity, and quality of life after 16 weeks.[480] Retrospective observational studies have reported the successful use of bosentan in pediatric patients with PAH.[481,482]

Ambrisentan is a relatively ET_A-selective antagonist. In concurrent double-blind, placebo-controlled studies of patients with PAH, 5 and 10 mg daily of ambrisentan for 12 weeks resulted in placebo-corrected improvements in 6MWD of 31 and 51 m, respectively, in one trial, and 32 and 59 m with 2.5 and 5 mg treatments, respectively, in the other trial.[483] A delay in the time to clinical worsening was seen in one of the trials, and health-related quality of life improved in both. In open-label extension studies, ambrisentan therapy was accompanied by improved hemodynamic values at a median duration of more than 1 year and persistent improvements in exercise capacity at 2 years.[484,485] Lower rates of elevated transaminases are observed with ambrisentan than bosentan and the FDA label requirement for monthly liver function monitoring has been removed for ambrisentan, although experts continue to recommend intermittent evaluations. Notable side effects include peripheral edema, anemia, and nasal congestion. Endothelin receptor antagonists as a class are teratogenic, and contraception and pregnancy testing are required for use in women with childbearing potential.

The third and most recently approved endothelin receptor antagonist is the dual ET_A/ET_B antagonist macitentan. The approval of macitentan was based on the first event-driven randomized controlled study in PAH (SERAPHIN).[486] This study represented the first shift from short-term surrogate endpoint trials in PAH to a long-term, larger morbidity or mortality trial. With 742 randomized patients with median double-blind treatment duration of 115 weeks, SERAPHIN was then the largest and longest PAH trial to date. For the group receiving macitentan 10 mg daily, there was 45% reduction in primary events compared with the placebo group. The treatment benefits with macitentan 10 mg daily were driven mainly by lower rates of disease progression and PAH-related hospitalizations. Unlike earlier PAH trials, SERAPHIN allowed for stable background PAH therapy at the time of enrollment. At baseline, 63.7% were receiving either phosphodiesterase type 5 inhibitor or oral/inhaled prostanoid therapies. Improvements were observed for both patients who were PAH drug naïve or already on background therapy. Like the other two endothelin receptor antagonists, female patients of childbearing potential require the use of highly effective contraception and monthly pregnancy testing. Nasopharyngitis, headache, and anemia were noted more frequently in the macitentan group compared with placebo; rates of reported edema were similar between macitentan and placebo. Treatment with macitentan does not require additional monthly laboratory monitoring.

Macitentan was also studied in portopulmonary hypertension (PoPH,) a PAH subgroup typically excluded from other PAH trials.[309] In one prospective, 12-week, multicenter, double-blind, placebo-controlled, phase 4 study, macitentan 10 mg daily in PoPH demonstrated a 35% reduction in the primary endpoint of pulmonary vascular resistance (PVR). There were no differences in 6MWD or functional class, and no significant hepatic safety concerns. Edema, bronchitis, and anemia were reported more frequently in the macitentan group compared with placebo. Macitentan was also studied in Eisenmenger syndrome, with 226 patients randomized to either macitentan or placebo for 16 weeks.[487] As with the prior study of bosentan in Eisenmenger syndrome, no new safety signal was noted with macitentan in this population. There was no significant difference observed in the primary endpoint of change in 6MWD.

Nitric Oxide Pathway Therapies

The roles of phosphodiesterase type 5 inhibitors and soluble guanylate cyclase stimulator are considered below.

Phosphodiesterase Type 5 Inhibitors

The relative deficiency of nitric oxide (NO)-mediated vasodilation and modulation of cell growth in patients with PAH has led to attempts to augment its effects therapeutically in order to promote improvements in microvascular remodelling. NO acts through the second messenger cGMP, which is metabolized in the lung predominantly by phosphodiesterase type 5. Specific inhibitors of phosphodiesterase type 5 can promote acute pulmonary vasodilation by reducing the degradation of cGMP.[488]

In a double-blind, randomized, placebo-controlled trial of 278 patients predominantly with IPAH but also some with congenital heart or connective tissue disease, sildenafil administered orally at 20, 40, or 80 mg three times daily improved exercise capacity, hemodynamics, and functional class.[148] Although the time to clinical worsening was not affected in this single trial, the improvement in 6MWD (51 m compared with baseline) was maintained over 1 year among the subset of patients continuing open-label use of sildenafil at 80 mg three times daily. The FDA-approved dosage for treatment of PAH is 20 mg by mouth three times daily, as there was no difference observed in among the doses in the primary endpoint. In open-label follow-up of a subset of patients up to 3 years following 12 weeks of randomized therapy with sildenafil, 46% demonstrated continued improvement over baseline exercise capacity, although additional therapies had been added to sildenafil during this period.[489] An initial 12-week, double-blind, placebo-controlled trial of sildenafil for treatment of PAH in children aged 1 to 18 years demonstrated efficacy in improving exercise capacity and hemodynamics at some doses, although the optimal regimen requires further study.[490]

The longer-acting phosphodiesterase type 5 inhibitor tadalafil was studied in a 16-week, double-blind, placebo-controlled trial of PAH with 53% already on stable background bosentan therapy.[149] Four different doses of tadalafil were studied, ranging from 2.5 mg up to 40 mg daily. The overall treatment effect was a 33-m improvement in 6MWD at 16 weeks (although statistically significant only for the highest dose group, 40 mg daily). The time to clinical worsening and quality of life also improved. The mean improvement in 6MWD was greater among the treatment-naïve participants (44 m) than those already receiving bosentan (23 m). During open-label extension for up to 1 year, improvements in 6MWD in patients receiving either 20 or 40 mg daily of tadalafil appeared to be maintained.[491]

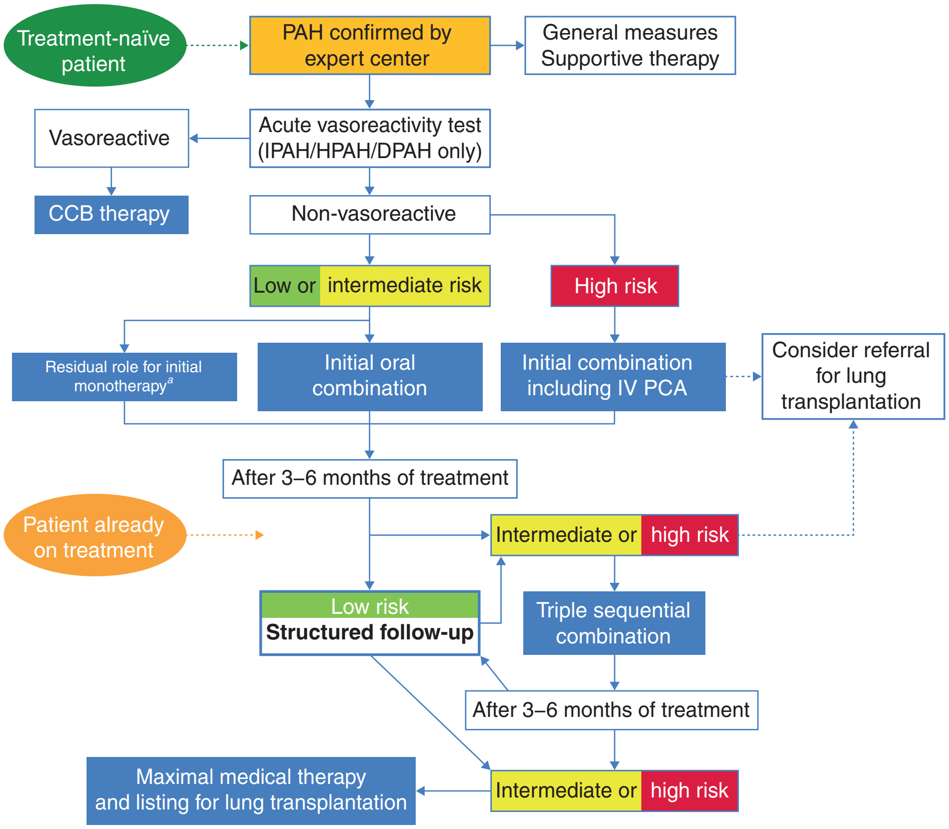
Common side effects of phosphodiesterase type 5 inhibitors used to treat PAH are headache, flushing, diarrhea, epistaxis, and myalgias. Systemic hypotension also has occurred, particularly with concomitant nitrate use, and this combination should be avoided.

Soluble Guanylate Cyclase Stimulator Riociguat is an orally administered guanylate cyclase stimulator that augments cGMP differently than phosphodiesterase type 5 inhibitors. Riociguat can work either in conjunction with endogenous NO or in the absence of NO to produce cGMP. Riociguat has demonstrated safety and benefit both in patients with PAH and in those with inoperable CTEPH.[492,493] The PATENT-1 study in PAH randomized 443 patients into three groups: placebo, 1.5 mg three times per day, and an uptitrated dose to a maximum of 2.5 mg three times per day. By week 12, treatment effect of 36 m was observed between the 2.5-mg group and the placebo group. There were also significant improvements in secondary endpoints in PVR, NT-proBNP levels, WHO function class, time to clinical worsening, and Borg dyspnea score. The most commonly reported side effects were headache (27%), dyspepsia (19%), and peripheral edema (17%). In the open-label extension study PATENT-2, sustained improvements in 6MWD were observed out to 1 year.[494] No new treatment-related adverse events were noted.

■ Combination Pharmacotherapy

There is a growing body of evidence in PAH that favors treating more than one pathway with combination PAH-targeted therapies. With rare exceptions, combination therapy is now the standard of care for the treatment of PAH (Fig. 72-14).[434] The first major signal ushering in combination therapy in PAH came from the PACES study.[495] A total of 267 PAH patients receiving chronic intravenous epoprostenol infusion therapy were randomized to receive either sildenafil or placebo for 16 weeks. There was a placebo-adjusted increase of 28.8 m in the primary endpoint of 6MWD in patients receiving sildenafil therapy (titrated up to maximum 80 mg three times daily). There was also significant difference in time to clinical worsening, which was one of the secondary endpoints of the study. Notably, 7 deaths occurred in the placebo group versus none in the sildenafil group. This was the first study to suggest that combining therapies may confer a survival benefit over monotherapy.

The pivotal evidence for up-front combination therapy came from the AMBITION study with 500 newly diagnosed PAH patients in functional class II or III randomized to receive monotherapy versus combination of approved therapies in an event-driven study.[496] The patients received either ambrisentan (10 mg) or tadalafil (40 mg) alone (starting with half the dose of each and titrated to full dose over 4 weeks), whereas the combination group received both agents titrated to full doses over a period of 8 weeks following randomization. The primary endpoint was time to first occurrence of death, hospitalization for worsening PAH, disease progression, and predefined unsatisfactory long-term clinical response. The combination group saw a 50% reduction in primary endpoint compared with the pooled monotherapy group (HR, 0.50; $p < 0.001$). Additional efficacy endpoints at week 24 demonstrated that the combination group was superior to the pooled monotherapy group in reduction of NT-proBNP, satisfactory clinical response composite



Treatment-naïve patient
PAH confirmed by expert center
General measures Supportive therapy
Vasoreactive
Acute vasoreactivity test (IPAH/HPAH/DPAH only)
CCB therapy
Non-vasoreactive
Low or intermediate risk
High risk
Residual role for initial monotherapy[a]
Initial oral combination
Initial combination including IV PCA
Consider referral for lung transplantation
After 3–6 months of treatment
Patient already on treatment
Intermediate or high risk
Low risk
Structured follow-up
Triple sequential combination
After 3–6 months of treatment
Maximal medical therapy and listing for lung transplantation
Intermediate or high risk

Figure 72-14 PAH treatment algorithm: World Symposium PH 2018. [a]See Table 19 in Ref. 399. *(Reproduced with permission from Galiè N, Channick RN, Frantz RP, et al. Risk stratification and medical therapy of pulmonary arterial hypertension. Eur Respir J. 2019;53(1):1801889.)*

at week 24, and improvement from baseline 6MWD. The combination therapy group reported more peripheral edema, headache, nasal congestion, and anemia compared with the monotherapy groups. The discontinuation rates were the same across the three treatment groups.

The results of AMBITION and observations from PACES are now reflected in current PAH treatment guidelines, which recommend combination treatment strategy. The exceptions for using monotherapy include cases of acutely vasoreactive PAH benefiting from CCB monotherapy, and existing PAH patients who are maintaining low-risk assessment status and continued benefit from monotherapy.[434] In certain newly diagnosed PAH patients with concerns for comorbidities that may either limit response to PAH therapy or cause tolerance issues (e.g., cases that may have been excluded from AMBITION study inclusion due to select comorbidities), starting with monotherapy may be justified.[434]

Two notable uncontrolled studies highlighted the hemodynamic impact of initial combination therapy in newly diagnosed PAH patients. One retrospective report looked at newly diagnosed IPAH patients (all function class III or IV at baseline) treated with up-front triple combination therapy including intravenous epoprostenol, bosentan, and sildenafil.[497] By 4 months follow-up, PVR went from a baseline of 1718 ± 627 dyn • s • cm^{-5} to 564 ± 260 dyn • s • cm^{-5}. At subsequent follow-up, all 18 patients were improved to functional class I or II with sustained improvements in hemodynamics and 6MWD. The same center also coordinated the prospective, phase 4 OPTIMA study, which investigated the safety and efficacy of combining macitentan and tadalafil up front in newly diagnosed PAH patients.[498] In this single-arm study of initially 46 subjects, the combination of macitentan and tadalafil resulted in a 47% reduction in PVR (reduction of 416 dyn • s • cm^{-5} from baseline) by week 16. Despite the limitations of a single-arm study and caution with comparing across reports, this magnitude of PVR reduction was not observed in prior hemodynamic studies with either endothelin receptor antagonist (bosentan: reduction of 223 dyn • s • cm^{-5} from baseline)[475] or phosphodiesterase type 5 inhibitor (sildenafil: reduction of 122 dyn • s • cm^{-5} from baseline)[148] as monotherapy agents.

The benefits of combination strategy appear not to be limited to newly diagnosed PAH patients. The large event-driven studies with macitentan (SERAPHIN), selexipag (GRIPHON), and oral treprostinil (FREEDOM V) predominantly were with prevalent PAH patients with study drug added on top of background therapy/therapies. In all three studies, the added combination therapy was associated with lower rates of disease progression and hospitalizations related to PAH. In a proof-of-concept hemodynamic study with selexipag, 43 PAH patients on background endothelin receptor antagonist and/or phosphodiesterase type 5 inhibitor were randomized to either selexipag or placebo for 17 weeks.[499] The selexipag-treated group saw a PVR reduction of 30.3% compared with the placebo group. The ATHENA-1 study enrolled 33 PAH patients with suboptimal response to phosphodiesterase type 5 inhibitor monotherapy and added ambrisentan.[500] This single-arm, hemodynamic, observational study noted a 32% reduction in PVR by 24 weeks after addition of ambrisentan. In the PATENT-1 study, which led to the approval of riociguat for PAH, half of the patients were already on background PAH therapy and still benefited from the addition of riociguat.[492]

Although evidence currently favors combination over monotherapy in PAH, whether an early proactive sequential add-on approach yields similar results to up-front simultaneous start is unknown. The potential benefits of a sequential add-on approach in real-world practice include challenges with drug approval and procurement, as well as pinpointing and troubleshooting drug-related side effects. Combination therapy in PAH does not refer to combining agents within the same therapeutic pathway. For instance, phosphodiesterase type 5 inhibitor and riociguat taken together is contraindicated.

Current and future PAH clinical trials investigating new treatment pathways will need to demonstrate safety and efficacy on top of standard care—which now commonly is combination therapy.[400] Accordingly, the bar has been raised for new drug target discovery and begs for more efficient and responsible trial conduct.

NONPHARMACOLOGIC INTERVENTIONS FOR PAH

Lung transplantation is addressed in Chapter 106. Here, it will suffice to note that lung transplantation remains an important consideration for some patients with PAH whose disease fails to respond adequately to medical therapy. Although changes in the method of allocating donor lungs within the United States have improved wait times, mortality on the wait list for patients with PAH remains excessive compared to patients with other indications for lung transplantation.[501] To help address this issue, PAH patients who are deteriorating despite optimal medical therapy, and who have a cardiac index <1.8 L/min/m^2 or a right atrial pressure >15 mm, may qualify for a lung allocation score exception.[502]

Balloon dilation atrial septostomy has been performed as a palliative measure, as well a "bridge" to lung transplantation in some patients with severe PAH and symptoms refractory to other therapies. At the expense of worsening systemic oxygenation, the creation of a right-to-left shunt at the atrial level can help offload the struggling right ventricle and improve cardiac output and symptoms in carefully selected cases with PAH.[503] Controlled studies have not been performed, and evidence-based selection criteria have not been established. Right atrial pressure greater than 20 mm Hg prior to balloon dilation atrial septostomy has been associated with a 10-fold increase in mortality and is considered a contraindication. The procedure should be performed only at experienced institutions.[504]

Pulmonary artery denervation (PADN) applies the concept of renal denervation as means of potentially modulating vascular tone to the pulmonary circulation.[505,506] Both radiofrequency ablation and intravascular ultrasound-based techniques have been reported.[507] PADN remains an experimental therapy in PAH, lacking controlled data and standardization and in need of validation.

CHAPTER 73

Pulmonary Thromboembolic Disease

Timothy M. Fernandes
Peter F. Fedullo

INTRODUCTION

Pulmonary thromboembolic disease refers to the condition in which blood clot(s) (thrombus or multiple thrombi) migrate from the systemic circulation to the pulmonary vasculature (Fig. 73-1). The field of pulmonary thromboembolic disease has continued to evolve, and aspects of clinical care remain shrouded in controversy. What is certain is that the incidence of pulmonary embolism (PE) appears to be increasing over the past few decades, probably reflecting an increase in the availability and sensitivity of CT scanning. Despite this increase in diagnosis, the mortality related to acute PE continues to decline.

Most of the thrombi arise from the deep veins of the lower and upper extremities (deep venous thrombosis, DVT). From a clinical perspective, DVT and PE can be considered a continuum of the same disease, and the two terms are often collectively referred to as *venous thromboembolism (VTE)*. For the purposes of this chapter, we will focus on PE.

EPIDEMIOLOGY

The exact annual incidence of PE in the United States remains uncertain but appears to be increased in incidence in recent years.[1] In a retrospective analysis of data involving 2218 Olmsted County residents over a 10-year period, community residents who were not hospitalized within a 90-day period had an incidence of PE of 3.6 (95% confidence interval [CI], 3.2–4.0) per 10,000 person-years.[2] A slightly lower incidence of 2.3 per 10,000 person-years was reported in an earlier study in Massachusetts.[3] This translates to an annual incidence of approximately 100,000 cases in the United States. However, the true incidence of PE is likely to be much higher since many cases remain undiagnosed. A systematic review revealed that silent PE was present in 32% of patients with DVT.[4] An earlier report estimated that as many as 630,000 patients develop PE every year in the United States with 200,000 related deaths, the majority in patients in whom the diagnosis was never made.[5]

Although considerable effort is directed toward the development of new diagnostic techniques and therapeutic agents, a considerable impact on PE-related mortality has resulted from the routine use of prophylactic strategies, an understanding of the often subtle clinical presentation of the disease, the appropriate application of existing diagnostic techniques, and the use of newer treatment modalities associated with better outcomes. This has translated to decreased PE-related mortality in recent years. In the RIETE Registry, the 30-day PE-related mortality decreased from 3.3% in 2001 to 1.8% in 2013 ($p < 0.01$) (Fig. 73-2).[6,7]

SOURCES OF EMBOLI

Most cases (80%–95%) of PE occur as a result of thrombus originating in the lower extremity. Thrombus often begins at a site where blood flow is turbulent, such as at a venous bifurcation or behind a venous valve (Fig. 73-2). When thrombus propagation exceeds the rate of thrombus organization and adherence to the endothelium, part or all of the thrombus may break away and migrate via the venous system to the lungs. Most thrombi originate in the deep veins of the calf (anterior tibial, posterior tibial, and peroneal veins) and propagate proximally to the popliteal and femoral veins. Calf-limited thrombi pose a minimal embolic risk, while those that extend into and above the popliteal vein represent the most common source of acute symptomatic pulmonary embolism. This is not meant to imply that calf-limited thrombosis represents a benign condition, though, as proximal propagation may occur in as many as 15% of untreated patients along with a higher risk of thrombotic recurrence and postthrombotic syndrome.[8]

Emboli may originate from other sources, most often from the pelvic veins—in which case a predisposing factor such as pregnancy, uterine fibroids, pelvic thrombophlebitis or pelvic infection, prostate disease, or recent pelvic surgery can often be identified. Emboli may also originate from upper-extremity thrombosis, which is frequently associated with central venous catheters or intravascular cardiac devices, or may be associated with thoracic outlet obstruction or effort thrombosis (Paget-Schroetter syndrome).[9] A small number of patients with PE may have evidence of right ventricular thrombus (so-called clot in transit) at presentation, and this has been associated with more hemodynamic instability and an increase in mortality.[10,11]

PREDISPOSING FACTORS

The nomenclature used to describe the predisposing factors for acute PE has changed over the last decade. Terms previously used such as *provoked* or *unprovoked VTE* no longer appear in most recent iterations of guidelines issued by the European Respiratory Society and the American College of Chest Physicians.[7,12] Newer terminology favors describing the treatment of PE as the initial phase pertaining to the first 3 months of anticoagulation and the extended phase. Patients with lower risk for recurrence can stop anticoagulation after the initial phase, while those with higher risk for recurrence should consider extended anticoagulation. Patients who have major transient risk factors (such as major surgery, estrogen therapy,

pregnancy, leg injury, air flights >8 h, or prolonged medical hospitalization) for VTE can consider stopping anticoagulation after the first 3 months, whereas indefinite anticoagulation is favored for those with no identifiable risk factor or a persistent risk factor (malignancy, certain hypercoagulable states).

Rudolf Virchow first described the phenomena of "embolism" and "thrombosis" in the mid-nineteenth century, and three main factors contributing to the formation of venous thrombosis (Virchow's triad) are attributed to his work: venous stasis, hypercoagulability, and injury to the venous wall (endothelium).[13] One hundred fifty years later, this basic classification remains useful in helping clinicians stratify an individual patient's risk of developing VTE (Table 73-1). Inflammation, while not part of the classic Virchow triad, is common to all three components of the triad and is a shared feature of many of the medical conditions that predispose to VTE. It is important to recognize that there is an interplay between acquired (Table 73-2) and genetic risk factors leading to the development of DVT and/or PE, and that multiple factors can often be found in individual patients.

TABLE 73-1 Virchow's Triad: Clinical States Predisposing to Venous Thrombosis

Stasis	Immobility Bed rest Anesthesia Congestive heart failure/cor pulmonale Prior venous thrombosis
Hypercoagulability	Malignancy Anticardiolipin antibody Nephrotic syndrome Essential thrombocytosis Estrogen therapy Heparin-induced thrombocytopenia Inflammatory bowel disease Paroxysmal nocturnal hemoglobinuria Disseminated intravascular coagulation Protein C and S deficiencies Antithrombin III deficiency
Vessel wall injury	Trauma Surgery

■ Transient Risk Factors

The risk imposed by a major surgical procedure is well recognized. Without prophylaxis, venous thrombosis occurs after approximately 20% of all major surgical procedures with associated embolism in 1% to 2% of cases.[14] The incidence of thromboembolism without prophylaxis is even higher in orthopedic patients with over 50% of major orthopedic procedures complicated by venous thrombosis. In the absence of prophylaxis, the frequency of fatal postoperative PE ranges from 0.1% to 0.4% in patients undergoing elective general surgery and from 1% to 5% in patients undergoing elective hip or knee surgery, emergency hip surgery, major trauma, or spinal cord injury.[15] Although surgery is a major transient risk factor for development of VTE, there is a low risk of recurrent VTE after the initial 3 months of therapy, with a recurrence rate of 3% within 5 years after the event.

Major traumatic injuries, most notably those of the head, spine, lower limbs, and pelvis, are also associated with high risk of VTE. The basis for this risk is multifactorial, involving all three components of Virchow's triad. Among patients in a trauma unit, 56% those with lower limb or pelvic fractures had evidence of DVT, while 40% of patients with injuries to the face, chest, or abdomen had DVT.[16]

Although initially recognized and studied in surgical patients, it is now appreciated that hospitalized medical patients may be equally prone to developing DVT.[17] In about 80% of cases, one or more risk factors may be present when extensive investigative testing is performed. Major risk factors include New York Heart Association class III and IV congestive heart failure, chronic obstructive pulmonary disease, sepsis and other inflammatory disorders, recent myocardial infarction, advanced age, stroke, critical illness, and prolonged bed rest.

Any prolonged period of immobilization may increase thromboembolic risk and explains the occurrence of thrombosis under such circumstances as paralysis, bed rest, and prolonged air travel. Long-distance traveling (economy class syndrome) is associated with a 1.5- to 3-fold increase in thromboembolic risk, depending on the travel duration.[18] Despite the relative increase in risk, the actual incidence of PE associated with air travel is quite low.[19]

TABLE 73-2 Predisposing Factors for Venous Thromboembolism

Strong risk factors (OR >10)
Fracture of lower limb
Hospitalization for heart failure or atrial fibrillation/flutter (within previous 3 months)
Hip or knee replacement
Major trauma
Myocardial infarction (within previous 3 months)
Previous VTE
Spinal cord injury
Moderate risk factors (OR 2–9)
Arthroscopic knee surgery
Autoimmune diseases
Blood transfusion
Central venous lines
Intravenous catheters and leads
Chemotherapy
Congestive heart failure or respiratory failure
Erythropoiesis-stimulating agents
Hormone replacement therapy (depends on formulation)
In vitro fertilization
Oral contraceptive therapy
Post-partum period
Infection (specifically pneumonia, urinary tract infection, and HIV)
Inflammatory bowel disease
Cancer (highest risk in metastatic disease)
Paralytic stroke
Superficial vein thrombosis
Thrombophilia
Weak risk factors (OR <2)
Bed rest >3 days
Diabetes mellitus
Arterial hypertension
Immobility due to sitting (e.g., prolonged car or air travel)
Increasing age
Laparoscopic surgery (e.g., cholecystectomy)
Obesity
Pregnancy
Varicose veins

HIV = human immunodeficiency virus; OR = odds ratio; VTE = venous thromboembolism.

Data from Vandenbroucke JP, Rosing J, Bloemenkamp KW, et al. Oral contraceptives and the risk of venous thrombosis. N Engl J Med. 2001;344(20):1527–1535 and Vinogradova Y, Coupland C, Hippisley-Cox J. Use of hormone replacement therapy and risk of venous thromboembolism: nested case-control studies using the QResearch and CPRD databases. BMJ. 2019;364:k4810.

Pregnancy is the most common cause of VTE in women less than 40 years old, and if untreated it may account for 20% to 50% of all pregnancy-related deaths. Compared with nonpregnant women, the risk of venous thrombotic events is increased 5-fold during pregnancy and 60-fold in the first 3 months after delivery.[20,21] The increase may be a result of decreased mobility, pregnancy-related hypercoagulable state (increases in factors II, VII, VIII, and X, acquired activated protein C resistance, decreased free protein S level), and venous obstruction from uterine compression. The incidence is estimated at 0.76 to 1.72 cases per 1000 pregnancies and occurs in roughly equal distribution over all trimesters. Most cases of postpartum DVT occur within the first 6 weeks after delivery. Cesarean section, premature birth, multiple births, preeclampsia, advanced maternal age, and maternal history of cardiac disease have all been identified as contributing factors. Interestingly, 90% of all pregnancy-related DVT cases are noted in the left leg, presumably because of the anatomic relationship between the uterus and inferior vena cava.[22]

The use of oral contraceptive agents and hormonal replacement therapy has also been associated with an increased risk of VTE.[23,24] Although the risk of VTE is higher among users of oral estrogen-containing contraceptives, the absolute risk is low. In terms of oral contraceptive agents, the relative risk of developing venous thrombosis is increased four- to sixfold. There appears to be a synergistic effect of oral contraceptives with obesity.[25]

Hormone replacement therapy appears to be associated with a two- to fourfold increased risk of VTE.[26] Studies have suggested that venous thromboembolic risk is lower with transdermal hormone preparations.[24] However, none of these studies involved randomized trials. Given that the baseline risk of thrombosis increases with age, the use of hormonal replacement therapy in a postmenopausal population has a considerably higher impact on absolute rates of thrombosis.

Obesity has been associated with VTE, particularly in women. The Nurses' Health Study found that a body mass index greater than or equal to 29 kg/m^2 was an independent risk factor.[27] The metabolic syndrome, defined by abdominal obesity, elevation of blood pressure, elevated fasting blood sugar and triglycerides, and low levels of high-density lipoprotein cholesterol, appears to be associated not only with an increased risk of atherosclerotic disease but also of VTE.[28]

The risk of VTE increases with age. A recent study, using hospital discharge surveys over a 21-year period, found that patients 70 years or older have an approximately 25-fold increased risk, compared with those 20 to 29 years of age.[29] Presumably, the difference may be due to decrease in mobility and increase in comorbidities in this population. Although PE is suspected less commonly prior to death in elderly patients, they appear to have a higher mortality due to PE.

■ Persistent Risk Factors

Patients with cancer, particularly those with primary malignancies from lung, pancreas, brain, ovary, and stomach/colorectal tracts, are at a high risk for VTE.[30] Cancer is estimated to increase the risk of VTE four- to sixfold. Patients with cancer also have a higher risk of thromboembolic recurrence and have a higher overall mortality rate than cancer patients without thrombosis. Multiple factors are probably involved and include the development of abnormalities in the hemostatic system related to the malignancy itself as well as those induced by chemotherapeutic agents, immobility, infectious complications, and the presence of chronic indwelling central venous catheters. Although most instances of cancer-associated VTE occur after the diagnosis of the malignancy, approximately 5% to 10% of patients with idiopathic venous thrombosis have a malignancy diagnosed within the next 2 to 3 years. There is no evidence at this time to recommend an aggressive search for cancer (such as routine CT of the abdomen and pelvis in search of a malignancy) in patients with idiopathic thrombosis.[31] Age-appropriate cancer screening (including colonoscopy, mammogram, and PAP smears) should be recommended in all patients with VTE.

Various hematologic conditions such as polycythemia vera, essential thrombocytosis, and acute promyelocytic leukemia may result in significant overproduction of different cell lines, which in turn may increase the risk of VTE by increasing blood viscosity (hyperviscosity syndromes) and through the release of procoagulants.[32,33] This type of thrombosis seems to occur more frequently in the hepatic or portal veins and may be the presenting symptom of the underlying disorder.

Paroxysmal nocturnal hemoglobinuria is a rare condition associated with a VTE incidence of approximately 40%.[34] Many cases involve non–lower extremity sites, particularly in the intra-abdominal vessels. The reason for thrombosis is not clear but may be related to a decrease in blood complement levels in these patients.

The presence of antiphospholipid antibodies, most notably the lupus anticoagulant, appears to be an independent risk factor for VTE.[35] Among patients with venous thrombosis, a lupus anticoagulant has been reported in 5% to 15%, and this abnormality has been estimated to lead to a ninefold increased risk of thrombosis. Among patients with antiphospholipid antibody syndrome, those with triple positivity (positive dilute Russell viper venom testing, anti-aβ2GPI, and anticardiolipin antibody testing) are at high risk for recurrent VTE and benefit from use of warfarin rather than any of the direct oral anticoagulants.[36]

The frequency of VTE in patients with nephrotic syndrome may be as high as 40%.[37] There is a higher tendency for the thrombosis to present in unusual locations such as the cerebral sinus or as arterial thrombosis. Rarely, thrombosis may also be the presenting symptom of the nephrotic syndrome. The mechanism for VTE in these patients is not clear, but various factors such as functional or quantitative changes in coagulation factors like acquired deficiency in proteins C and S, diminished fibrinolytic activity, platelet hyperreactivity, and increase blood viscosity have been proposed.

Patients with inflammatory bowel disease are at substantially increased risk of both venous and arterial thrombosis.[38] The exact pathogenic mechanism remains unclear. The majority of thrombotic complications occur during an active phase of the disease, and inflammatory mechanisms have been proposed.

■ Inherited Risk Factors

Many patients who develop VTE are found to have an inherited risk factor due to either abnormal levels or functional abnormalities of coagulation factors (inherited thrombophilia). The relative risk of thrombosis varies widely depending on the hemostatic defect. In general, this group of patients tends to be younger (<50 years) and has a tendency to develop recurrent VTE.[39]

The first known inherited thrombophilic trait was antithrombin III deficiency, originally described in 1965. Subsequently, a number of other genetic mutations associated with VTE have been reported. The most common of these inherited predispositions was first described in 1993 by Dahlbeck and designated as a factor V Leiden mutation.[40] It is the consequence of a single point mutation on the factor V gene (adenine for guanine), resulting in factor Va having diminished sensitivity to the natural anticoagulant effect of activated protein C. Approximately 5% of Caucasians in Europe and North America are heterozygous for this genetic defect; lower rates of carrier frequency have been reported among Native American, African, and Asian populations. The heterozygous state carries a 5- to 10-fold increase in lifetime risk for VTE, whereas the risk among patients homozygous for this mutation may be increased 80-fold. Factor V Leiden mutation appears to be an important risk factor for VTE during pregnancy, in the postpartum period, and during oral contraceptive use.[41] Compared with women who do not use oral contraceptives and are not carriers of the factor V mutation, the risk of thrombosis among those with both risk factors is increased approximately 30-fold.[42]

Another common mutation has been identified in the 3′ untranslated region of the prothrombin gene (substitution of A for G at position 20210) and is present in 2% to 4% of the general population.[43] This mutation results in an overproduction of prothrombin, which is otherwise functionally normal. It is associated with a three- to fourfold increased risk of lower extremity venous thrombosis and appears to act in a synergistic manner with other forms of thrombophilia in increasing both the initial and recurrent thrombosis risk.

In clinical practice, factor V Leiden mutation and prothrombin gene mutation are the most common inherited conditions (5% and 3% of Caucasians, respectively, carry one copy of the gene) and account for more than half of the cases of inherited thrombophilia-related VTE. While presence of these mutations increases the risk for recurrence of VTE on a population scale, the effect of these mutations on an individual's risk for recurrence is negligible (hazard ratio [HR] for recurrence in patients with inherited thrombophilia compared to VTE patients without an inherited thrombophilia, 1.50; 95% CI, 0.82–2.77; $p = 0.187$), and therefore routine evaluation of factor V Leiden or prothrombin gene mutation after a VTE is unnecessary.[44] Three other conditions (deficiencies in antithrombin III, protein C, or protein S) account for most of the remainder of the inherited thrombophilias. Occasionally one may also encounter patients with VTE who may have other conditions, particularly related to dysfibrinogenemias. It is important to recognize that when multiple inherited risk factors coexist (such as factor V Leiden and prothrombin gene mutation), the risk of recurrent VTE may increase substantially, and lifelong anticoagulation may be necessary in these patients.

PATHOPHYSIOLOGY

Once detached from their point of origin, emboli travel via the systemic venous system, through the right chambers of the heart, and eventually reach the pulmonary arterial system. The physiologic effects and clinical consequences of pulmonary thromboembolism vary widely, ranging from asymptomatic disease to hemodynamic collapse and death. Major factors that determine the outcome include (1) size and location of emboli; (2) coexisting cardiopulmonary diseases; (3) secondary humoral mediator release and vascular hypoxic responses; and (4) the rate of resolution of emboli.

■ Hemodynamic Consequences

Obstruction of the pulmonary vascular bed by embolism acutely increases right ventricular afterload. Compensatory mechanisms exist that allow up to 70% obstruction of the pulmonary vascular bed before right ventricular failure develops.[45,46] The normal pulmonary arterial system is a low-pressure system capable of accommodating substantial increases in blood flow with only modest increases in pressure. The thin-walled right ventricle is poorly equipped to generate the pressure necessary to overcome any significant increase in pulmonary vascular resistance (Fig. 73-3).[7] Since the left and right ventricle share the same pericardial space (ventricular interdependence), the intraventricular septum begins to flatten in response to increases in right ventricular end-diastolic pressure (RVEDP); eventually, the septum bows into the left ventricle, which can impair cardiac output. The perfusion of the right coronary is determined by the difference between mean arterial pressure and

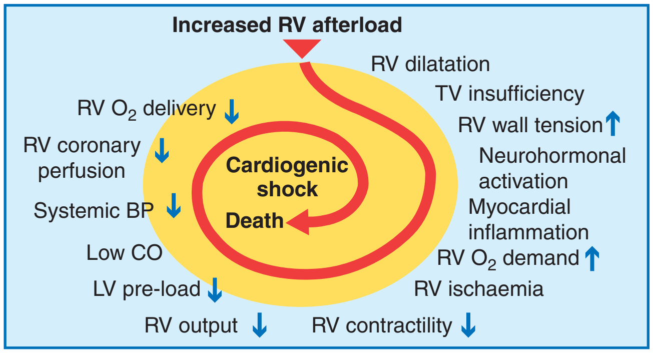

Figure 73-3 Increased right ventricular afterload leads to right ventricular ischemia and eventual cardiogenic shock. BP, blood pressure; CO, cardiac output; LV, left ventricular; RV, right ventricular; TV, tricuspid valve.

the RVEDP. As the RVEDP increases and cardiac output decreases in response to acute PE, there is a resultant decrease in perfusion to the right ventricle. This "RV death spiral" is common to all causes of right ventricular failure (i.e., pulmonary arterial hypertension, cor pulmonale, chronic thromboembolic pulmonary hypertension) but is especially severe in acute PE where the change is pressure is abrupt and the RV has not had time to hypertrophy in response to more gradual increases in afterload.

In the absence of preexisting cardiopulmonary disease, obstruction of less than 20% of the pulmonary vascular bed results in minimal hemodynamic consequences as a result of recruitment and distention of pulmonary vessels. When the degree of pulmonary vascular obstruction exceeds 30% to 40%, modest increases in right ventricular pressure occur, but cardiac output is maintained through an increase in heart rate and myocardial contractility. Compensatory mechanisms begin to fail when the degree of pulmonary artery obstruction exceeds 50% to 60%. Cardiac output begins to fall, and right atrial pressure increases dramatically. Mixed venous oxygen saturation falls, and a lactic acidosis may develop. With further acute obstruction, the right heart dilates, right ventricular wall tension increases, right ventricular ischemia may develop, the cardiac output falls, and systemic hypotension develops. In patients without prior cardiopulmonary disease, the maximal mean pulmonary artery pressure capable of being generated by the right ventricle appears to be 40 mm Hg (pulmonary artery systolic pressure of approximately 70 mm Hg).[45]

Other factors may affect the hemodynamic consequences of PE. Patients with preexisting cardiopulmonary disease often have diminished pulmonary vascular reserve, and even a relatively minor embolus may result in significant hemodynamic instability (Fig. 73-4). Alternatively, if the right ventricle has had time (months to years) to hypertrophy in response to a gradual increase in demand (left ventricular disease, idiopathic pulmonary arterial hypertension, chronic thromboembolism, etc.) a significantly higher pulmonary artery pressure may be seen.

Several observations suggest that other mechanisms are involved in hemodynamic consequences of acute PE. For example, patients develop only minimal hemodynamic instability during elective lobectomy, pneumonectomy, or even single lung transplantation despite complete and acute interruption of blood supply during cross clamping. Certain patients develop disproportionately large and fluctuating pulmonary hemodynamic changes in response to relatively small emboli, suggesting that other mechanisms such as reflex vasoconstriction and release of vasoactive compounds also may be involved.[47] There appears to be an imbalance between excessive vasoconstrictors such as serotonin, thromboxane, and endothelins and a loss of nitric oxide and prostacyclins that further exacerbates the hemodynamic consequences of the PE beyond the degree attributable to the obstruction alone.[48]

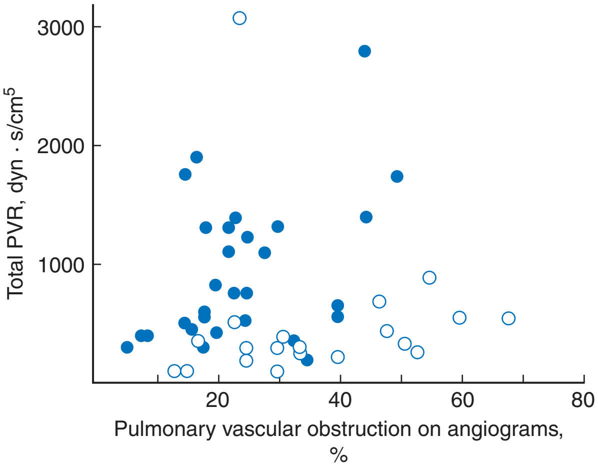

Figure 73-4 Hemodynamic consequences of pulmonary embolism and the underlying state of the pulmonary vasculature. Patients in whom the pulmonary vasculature was previously normal *(open circles)* develop little increase in pulmonary vascular resistance (PVR) until the clot burden exceeds 50%. In those with antecedent cardiopulmonary disease *(solid circles)*, the PVR increases appreciably with only modest clot burden. *(Reproduced with permission from Sharma GV, McIntyre KM, Sharma S, et al. Clinical and hemodynamic correlates in pulmonary embolism. Clin Chest Med. 1984;5(3):421–437.)*

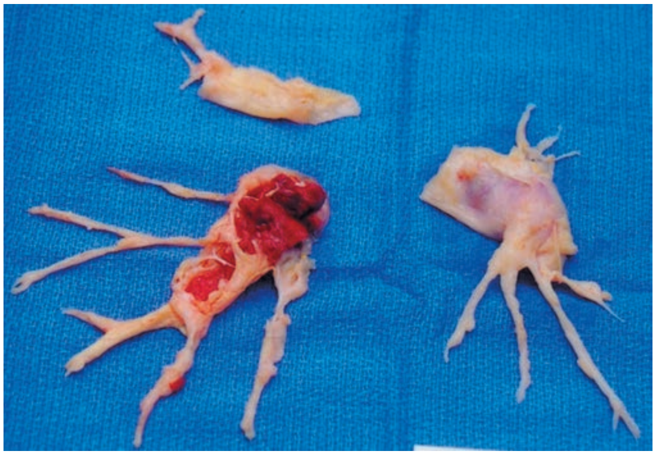

Figure 73-5 Chronic thromboembolic material dissected from pulmonary arteries at pulmonary thromboendarterectomy. Resolution of emboli is usually complete, but certain patients may be left with significant emboli residua.

As expected, large or multiple emboli tend to cause more severe symptoms and changes in oxygenation and hemodynamics. Given the large surface area of the peripheral pulmonary vascular bed compared with the central pulmonary vasculature, symptomatic improvement may occur when a large central embolus is fragmented by forces generated by cardiac contractions or even with chest compressions during cardiopulmonary resuscitation. Eventually, the emboli may either resolve by fibrinolysis, or organize and become scar-like tissue that adheres to the vascular endothelium (Fig. 73-5). Recent data suggest that complete resolution is uncommon and that as many as 50% of patients have some residual obstruction 6 months after the embolic event.[49,50]

■ Gas-Exchange Abnormalities

Hypoxemia is the most common immediate physiologic consequence of PE. Obstruction of the pulmonary vasculature prevents systemic venous blood from reaching the pulmonary capillaries of the involved vessels and redirects the blood flow to other parts of the pulmonary vascular bed. This results in an increase in ventilation–perfusion ($\dot{V}/\dot{Q}$) inequality, intrapulmonary shunting, and decreases in the mixed venous O_2 level, thereby magnifying the effect of the normal venous admixture.[51,52] Further shunting and increase in alveolar dead space can also occur as a result of alveolar hemorrhage or atelectasis related to loss of surfactant. Despite an increase in alveolar dead space, patients with pulmonary embolism often develop hypocapnia. This is thought to be due to hypoxia-induced intrapulmonary reflex vagal stimulation, with resulting hyperventilation. Finally, embolic events large enough to increase right atrial pressure may result in intracardiac right-to-left shunting through a patent foramen ovale.

TABLE 73-3 Incidence of Signs and Symptoms of Pulmonary Embolism

	Massive PE[a] (%)	Submassive PE[a] (%)	Without Pre-existing Cardiopulmonary Disease (%)[b]
Dyspnea	85	82	73
Pleuritic chest pain	64	85	66
Cough	53	52	37
Hemoptysis	23	40	13
Tachypnea	95 (>16 breaths/min)	87 (>16 breaths/min)	70 (>20 breaths/min)
Tachycardia (>100 beats/min)	48	38	30
Increased pulmonic component of second heart sound	58	45	23
Rales	57	60	51
Phlebitis	36	26	11

[b] *Data from Stein PD, Terrin ML, Hales CA, et al. Clinical, laboratory, roentgenographic, and electrocardiographic findings in patients with acute pulmonary embolism and no pre-existing cardiac or pulmonary disease. Chest. 1991;100(3):598–603.*

One uncommon consequence of PE is pulmonary infarction. Infarction is uncommon because the pulmonary parenchyma has three potential sources of oxygen: the pulmonary arteries, bronchial arteries, and airways. Two of these three sources must be compromised before infarction develops. Therefore, in a patient with no coexisting cardiopulmonary disease, infarction is rare, with about 16% of acute PE patients affected.[53,54] Infarction occurs in approximately 20% of patients with significant cardiac or pulmonary disease that compromises either bronchial arterial flow or airway patency. In patients with left ventricular failure, increased pulmonary venous pressure may decrease bronchial flow and infarction may occur.

DIAGNOSIS OF PULMONARY EMBOLISM

Highly sensitive D-dimer assays, stratification according to clinical assessment, and the application of Bayesian analysis, followed by imaging such as Doppler ultrasonography and/or computed tomography in the highest-risk patients, are the cornerstones of the diagnostic approach to suspected PE. Recognition of the clinical signs and symptoms associated with embolism is valuable because clinical findings and clinical suspicion represent an essential first step in the diagnostic pathway.

Clinical Presentation

The mainstay for the diagnosis of PE is a high index of suspicion tempered by the reality that most patients with embolism have one or more factors predisposing them to the condition. These predisposing factors need not be major or readily apparent. Recent surgery, a period of bed rest, medical comorbidities, or a minor traumatic injury can result in the development of VTE. The absence of a known clinical or thrombophilic predisposition, however, should not dissuade an objective evaluation if the clinical presentation is consistent with embolism.

Although a somewhat arbitrary classification (as presenting symptoms and signs of embolism frequently overlap), the presentation of acute PE can be categorized into one of three clinical syndromes: (1) isolated dyspnea; (2) pleuritic pain or hemoptysis; and (3) circulatory collapse.[55,56] The most common presenting symptom of acute embolism is the sudden onset of dyspnea.[55] Dyspnea usually occurs over minutes to hours, but in approximately 15% it occurs over days. Although usually present at rest, dyspnea may only be noted with exertion in certain cases. It is important to recognize that dyspnea does not occur in approximately 25% of patients ultimately proven to have embolism. Other symptoms include pleuritic chest pain, cough, leg swelling or pain, and hemoptysis. Hemoptysis is rare among patients suspected of having PE (5%), but its presence significantly increases the odds ratio (OR) that PE will be found (OR, 2.86; 95% CI, 1.36–6.03).[57] Syncope is rare among all patients with acute PE, but, among patients admitted with first episode of syncope, PE is ultimately found in 17% of patients.[58] The most common physical finding is tachypnea (respiratory rate >20/min), present in approximately 70% of patients with embolism. Less frequent physical findings include rales, tachycardia, and an increased pulmonic component of the second heart sound. Fever may develop some hours after the event and often reaches, but rarely exceeds, 38.3°C.[59]

These symptoms and signs are notably nonspecific (Table 73-3). In the PIOPED study, none of the presenting symptoms or signs with the exception of signs of DVT (unilateral leg swelling), jugular venous distention, and an increased pulmonic component of the second heart sound were significantly different between those with positive and negative CT angiograms.[55]

Assessment of Pretest Probability

A major advancement in the diagnostic approach to PE has been a transition from a purely technique-oriented approach to one that uses Bayesian analysis. In doing so, the pretest probability of the disease, derived independently of a particular test result using either empiric means or a standardized prediction rule, is calculated. This pretest probability aids in the selection and interpretation of further diagnostic tests to create a posttest probability of the disease. This posttest probability can then be used as a basis for clinical decision-making. For PE a number of such scores have been developed and validated. The Wells score is a prospectively validated, rapid, seven-item bedside assessment to estimate the clinical pretest probability for PE[60] (Table 73-4). An alternative scoring system, the YEARS criteria, was developed from the variables in the Wells score in combination with a D-dimer test; the presence of hemoptysis, signs of DVT, and PE as the most likely diagnosis, when combined with D-dimer, can reduce the need for CT scanning in patients with suspected PE[57] (Fig. 73-6).

Laboratory Findings

Routine laboratory testing is not useful in confirming or excluding the diagnosis of PE but may be helpful in suggesting other diagnoses. A modest leukocytosis may accompany embolism but rarely exceeds 20,000/mm^3.[61] A higher neutrophil-to-lymphocyte ratio (NLR) among patients with PE conveys a higher risk for 30-day mortality, but increased NLR, a nonspecific finding seen in many inflammatory conditions, is not helpful in establishing the diagnosis

TABLE 73-4 The Wells' Clinical Prediction Score

Variable	Points
DVT symptoms/signs	3.0
PE likely or more likely than alternative diagnosis	3.0
Heart rate >100	1.5
Immobilization/surgery previous 4 wk	1.5
Previous DVT or PE	1.5
Hemoptysis	1.0
Malignancy	1.0
Total Score	**Pretest Probability**
<2.0	Low
2.0–6.0	Moderate
>6.0	High
Dichotomized Score	
≤4	PE unlikely
>4	PE likely

Data from Wells PS, Anderson DR, Rodger M, et al. Derivation of a simple clinical model to categorize patients probability of pulmonary embolism: increasing the models utility with the SimpliRED D-dimer. Thromb Haemost. 2000;83(3): 416–420.

of PE.[62] As noted, hypoxemia is common in acute PE although the diagnosis cannot be excluded based upon a normal PO_2.[63,64] The more extensive the obstruction of the vascular bed, the more severe the hypoxemia is likely to be. However, many other conditions also cause hypoxemia, and embolism does not invariably cause hypoxemia or even a widening of the $(A\text{-}a)O_2$ gradient. In the PIOPED trial, no combinations of blood gas values were identified that reliably excluded PE. Although most patients with embolism have a low Pa_{O_2}, low Pa_{CO_2}, and/or high $P(A\text{-}a)O_2$ gradient, the absence of such abnormal values, alone or in combination, did not exclude PE. Hypercapnia resulting from increased dead space ventilation is rare and appears with embolism only in patients with marked antecedent ventilatory limitation or when such limitation has been imposed because the patient is on controlled mechanical ventilation when embolism occurs.

■ Electrocardiogram

The electrocardiogram is nonspecific in the diagnosis of PE, and its major value may be in identifying other clinical disorders (e.g., acute myocardial infarction and pericarditis) that may present in a similar fashion. Findings in acute PE include tachycardia, T-wave changes, ST-segment abnormalities, incomplete right bundle branch block, and left- or right-axis deviation (Fig. 73-7).[65] Atrial arrhythmias may occur but appear to be more common in patients with underlying cardiopulmonary disease. The S1Q3T3 pattern, commonly considered to be specific for PE, is seen in only a minority of patients. Electrocardiographic findings can offer insight into the extent and hemodynamic consequence of the embolism. The electrocardiogram is rarely normal in the setting of embolism associated with right ventricular dysfunction. The presence of an S1Q3T3 pattern, right bundle branch block, or T-wave inversion in leads V1–V3 in a patient with embolism should suggest the presence of right ventricular dysfunction, and these findings at presentation are associated with increased mortality.[66]

■ Chest Radiography

Most patients with PE have abnormal but nonspecific chest radiographic findings.[55,67] Common radiographic findings include atelectasis, pleural effusion, pulmonary infiltrates, and mild elevation of a hemidiaphragm. Classic findings of pulmonary embolism—such as Hampton's hump (a pleural-based opacity) or decreased vascularity (Westermark sign)—are suggestive but infrequent

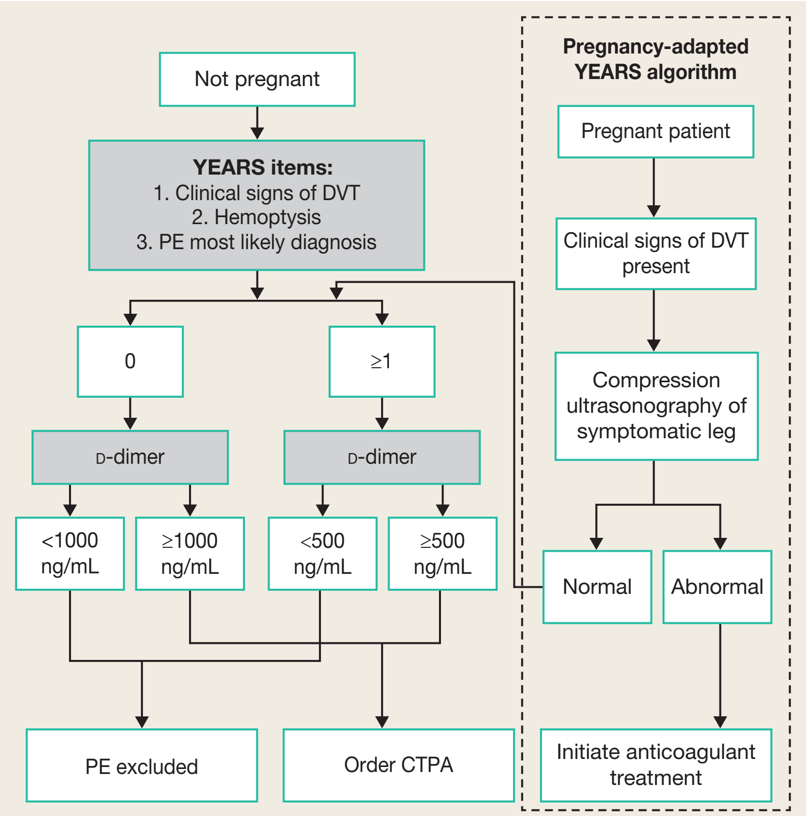

Figure 73-6 The YEARS Criteria along with D-dimer testing can be used in both pregnant and nonpregnant patients to exclude PE in the majority of patients without need for imaging. *(Reproduced with permission from MDCalc. www.mdcalc.com.)*

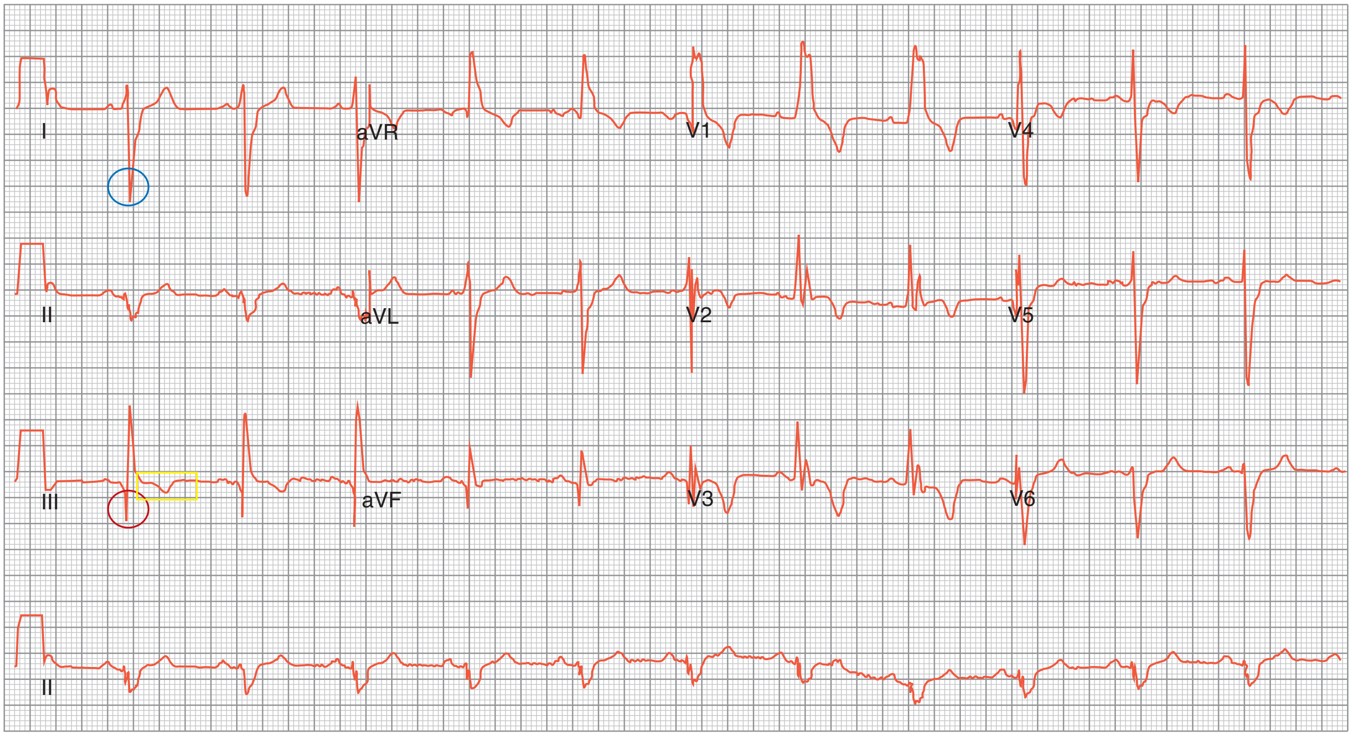

Figure 73-7 The S1Q3T3 pattern can be seen in right ventricular dysfunction such as acute PE.

(Fig. 73-8). There is some confusion about the diagnostic configuration of infiltrates due to embolism. These infiltrates, although usually abutting a pleural surface, can be of any shape, not necessarily wedge-shaped. Although pleural effusions occur in almost half of the patients, the majority of effusions are small and involve only blunting of the costophrenic angle. The main use of the chest radiograph in suspected embolism is to exclude diagnostic possibilities such as pneumothorax, which may simulate the disease. A normal chest radiograph in a patient with otherwise unexplained acute tachypnea, dyspnea, or hypoxemia should raise the possibility of embolism.

■ D-Dimer

The development of a rapid and accurate blood test capable of diagnosing VTE has been the subject of considerable investigative interest. A number of different hemostasiologic markers have been investigated. Of these, D-dimer, alone and in combination with other noninvasive studies, has been subjected to the most rigorous clinical evaluation.[68] D-Dimer testing has proved to be highly sensitive but not specific. Increased levels are present in nearly all patients with thromboembolism but also occur in a wide range of other circumstances, including advancing age, pregnancy, trauma, infections, the postoperative period, inflammatory states, and malignancy.

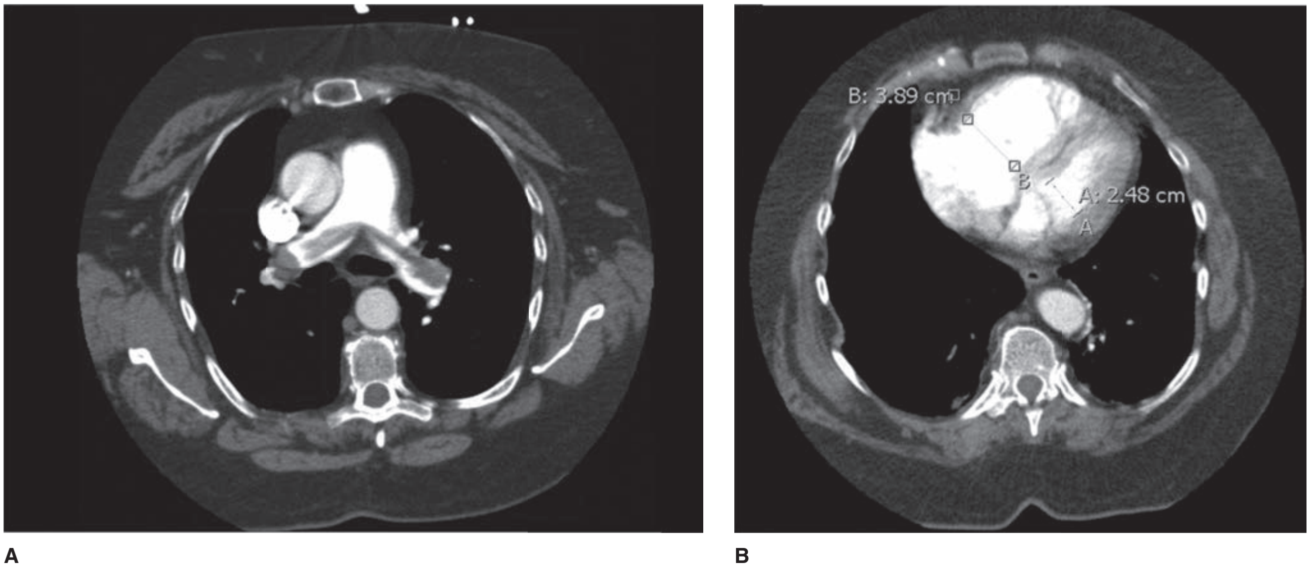

Figure 73-9 **A.** Computed tomographic angiography with classic finding of saddle pulmonary embolism. **B.** Images of the heart in the same patient demonstrate an increased RV:LV ratio and characteristic flattening of the intraventricular septum ("D-shaped septum") seen in submassive pulmonary embolism.

However, the high negative predictive value of a low D-dimer, especially in conjunction with the clinical signs and symptoms of VTE, make D-dimer testing an important tool to limit radiation exposure in outpatients presenting to the emergency departments with possible PE. The study is of limited utility in inpatients given the high frequency of positive results in this population.[69]

Multiple assays for D-dimer have been developed with a range of sensitivities and specificities.[70] Highly sensitive assays such as the enzyme-linked immunosorbent assay (ELISA) are capable of excluding thromboembolism when applied to the outpatient and emergency department patients in whom it has been well studied. Less sensitive assays (e.g., latex agglutination, red cell agglutination) lack the ability to exclude thromboembolism in isolation but have been used successfully in combination with either a clinical probability estimate or noninvasive diagnostic study. D-Dimer testing has been used successfully as part of a number of different diagnostic strategies. Negative results of standardized, highly sensitive assays (ELISA) have proved capable of safely excluding PE in outpatients presenting with a low or intermediate clinical likelihood of the disease.

■ Computed Tomography

Due to widespread availability, computed tomographic angiography (CTA) has become the first-line imaging test for PE (Fig. 73-9).[71] CT technology has evolved from single-detector scanners to 64-section multidetector row CT (MDCT) scanners. Using the latest-generation scanners, visualization of the entire chest with sub-millimeter resolution extending to the sixth-generation arteries can now be performed within a single breath hold. The PIOPED II trial, which used predominantly 4-MDCT technology and a composite reference standard, demonstrated sensitivity for the diagnosis of PE of 83%, specificity of 96%, positive predictive value of 86%, and negative predictive value of 97% (Table 73-5).[55] The predictive value of CT varied substantially when clinical assessment was taken into account, with the major variance occurring when there was discordance between the clinical assessment and CTA finding. Both the positive predictive value in patients with a low clinical probability and the negative predictive value in those with a high clinical probability were in the range of 60%. At the present time, CT can be considered confirmatory in excluding PE in patients with a low likelihood of disease and a negative CTA and confirming embolism in patients with intermediate or high probability of disease and a positive CTA. When discordance exists between the clinical assessment and CT findings, additional studies should be considered.

CTA can also provide additional information about the severity of the PE. A ratio of the right ventricle to left ventricle short-axis diameters (RV/LV) greater than 1 on the initial CT is predictive

TABLE 73-5 **Prevalence of Pulmonary Embolism in PIOPED II: Value of Correlating CT Interpretation with Clinical Assessment**

		Clinical Assessment		
		High No./Total (%)	Intermediate No./Total (%)	Low No./Total (%)
CT Scan Interpretation	**PPV of CTA**	22/23 (96%)	93/101 (92%)	22/38 (58%)
	PPV of CTA-CTV	27/28 (96%)	100/111 (90%)	24/42 (57%)
	NPV of CTA	9/15 (60%)	121/136 (89%)	158/164 (96%)
	NPV of CTA-CTV	9/11 (82%)	114/124 (92%)	146/151 (97%)

PPV of CTA, positive predictive value of computed tomographic angiography; PPV of CTA-CTV, positive predictive value of combined computed tomography angiography + venography; NPV of CTA, negative predictive value of computed tomographic angiography; NPV of CTA-CTV, negative predictive value of computed tomographic angiography + venography.
Data from Galli M, Luciani D, Bertolin G, et al. Lupus anticoagulants are stronger risk factors for thrombosis than anticardiolipin antibodies in the antiphospholipid syndrome: a systematic review of the literature. Blood. 2003;101(5):1827–1832.

TABLE 73-6 Pulmonary Embolism Rule-Out Criteria

Is the patient >49 years?
Is the pulse rate >99 beats per minute?
Is pulse oximetry <95% on room air?
Does the patient have current hemoptysis?
Is the patient taking exogenous estrogen?
Does the patient have a history of venous thromboembolism?
Has the patient had surgery or trauma requiring hospitalization in the past four weeks?
Does the patient have unilateral leg swelling?

Note: If the patient is considered to be at very low risk of pulmonary embolism (<15% risk) based on the physician's pretest suspicion, and answers "no" to all eight questions, the criteria results are considered negative.
Data from Kline JA, Courtney DM, Kabrhel C, et al. Prospective multicenter evaluation of the pulmonary embolism rule-out criteria. J Thromb Haemost. 2008;6(5):772–780.

of 3-month mortality and is important to the nomenclature of the acute PE (i.e., intermediate-low or intermediate-high risk), which is discussed in the upcoming risk stratification section.[7,72] Other findings that convey right ventricular dysfunction such as the reflux of contrast into the inferior vena cava and flattening of the intraventricular septum may be seen and have also been independently correlated with adverse outcomes in acute PE.[73]

Concerns have been raised that the widespread utilization of CTA is resulting in the overdiagnosis of embolism, defined as diagnosing clinically insignificant disease.[74] CTA has been compared to $\dot{V}/\dot{Q}$ for suspected PE, with comparable mortality and false-negative rates for the two imaging modalities but with a 35% higher rate of PE diagnosis for CT.[75] It has been suggested, based on the known natural history of subsegmental embolism, that patients with isolated subsegmental PE do not necessarily need to be treated with anticoagulants provided they have no evidence of DVT by ultrasonography of all four extremities.[12] Additionally, CTA, as a result of its easy availability, may be overutilized in outpatients without adequate patient screening through validated methods such as the Wells criteria/D-dimer model or the Pulmonary Embolism Rule-out Criteria (PERC) (Table 73-6).[76]

■ Ventilation–Perfusion Scanning

Ventilation–perfusion ($\dot{V}/\dot{Q}$) scanning had been the pivotal diagnostic test for suspected PE for many years but has been replaced by CT imaging. Despite limitations, $\dot{V}/\dot{Q}$ scanning can provide valuable information if used and interpreted appropriately. The PIOPED (Prospective Investigation of Pulmonary Embolism Diagnosis) trial provided valuable insight into the strengths and limitations of $\dot{V}/\dot{Q}$ scanning.[77] A negative study is capable of ruling out the diagnosis of PE with the same degree of certainty as a negative pulmonary angiogram and with a higher degree of certainty than can be achieved by a negative CT scan (Fig. 73-10). The positive predictive value of a "high-probability" study (one characterized by multiple, segmental-sized, mismatched defects) approximates 88%; when coupled with a high clinical probability of embolism, the positive predictive value increased to 96%. However, only 28% of patients in PIOPED had scans characterized as high probability or normal, the only categories that can be considered definitive. The majority of patients with embolism do not have a high-probability scan, while the majority of those without embolism do not have a normal scan.

There are certain situations in which $\dot{V}/\dot{Q}$ scanning may be preferred over CTA. IV contrast is not required for $\dot{V}/\dot{Q}$ scanning, making it a more desirable option in patients with renal dysfunction or a severe iodinated contrast allergy. In addition, with a portable gamma scintillation camera, the perfusion portion of the study can be performed at the bedside, which may be a major advantage in a critically ill patient for whom transportation to the CT scanner may be deemed too high risk. Preference for $\dot{V}/\dot{Q}$ scanning versus CTA in pregnancy remains controversial, although fetal risk due to radiation exposure appears to be low with both modalities.[78]

■ Echocardiography

Although transthoracic echocardiography (TTE) performs poorly in the diagnosis of acute PE with a sensitivity of only 50%,[79] certain findings of RV strain display high specificity that may be useful to "rule in" PE at the bedside in patients with a high pretest probability.[80] The classic echocardiographic finding of right ventricular free wall akinesis with sparing of the apex (McConnell's sign) has a 94% specificity for acute PE (Video 73-1).[81] Echocardiography may also disclose "clot in transit," which can be seen in about 5% of patients with acute PE.[11]

TTE has emerged as an important tool for risk assessment and treatment guidance in patients with acute PE. The presence of right

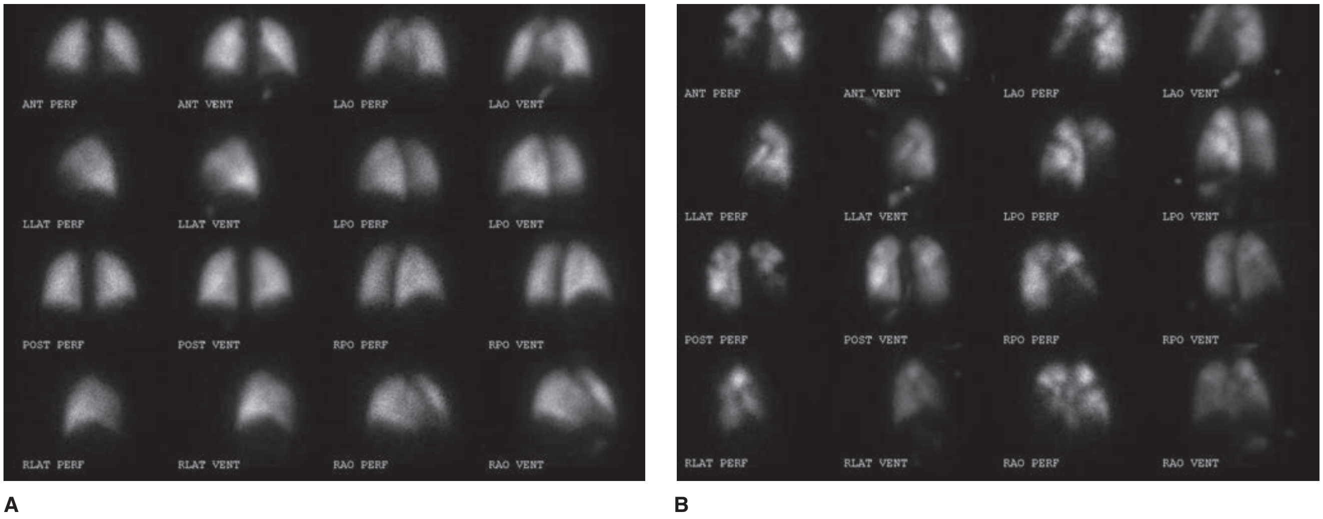

Figure 73-10 **A.** Normal ventilation images seen in the panels labeled VENT and matched normal perfusion in the panels labeled PERF. **B.** High-probability VQ scan with multiple segmental defects including the entire right lower lobe, right middle lobe, and segmental defects in the anterior left upper lobe and anteromedial basal left lower lobe.

ventricular dysfunction on a baseline echocardiogram in normotensive patients appears to represent an independent predictor of an adverse outcome or early death.[82] More specifically, four TTE parameters are independently associated with mortality: ratio of RV to left ventricular end-diastolic diameter, RV systolic pressure, tricuspid annular plane systolic excursion, and inferior vena cava collapsibility.[83] Echocardiography may also prove valuable in the evaluation of competing diagnostic possibilities such as right ventricular infarction, endocarditis, pericardial tamponade, and aortic dissection in patients with unexplained shock and evidence of elevated central venous pressure.

■ Lower Extremity Evaluation

Duplex ultrasonography, which refers to the combination of Doppler venous flow detection and real-time B-mode imaging, has assumed a central role in the noninvasive diagnosis of symptomatic lower extremity DVT.[84] A number of criteria are used to diagnose venous thrombosis, the most reliable of which is noncompressibility of a venous segment. Secondary, less reliable criteria include the presence of echogenic material within the venous lumen; venous distention; and loss of phasicity, response to Valsalva, and augmentation of spontaneous flow. The absence of an echogenic luminal mass cannot be considered useful in excluding the diagnosis of venous thrombosis because acute thrombus may not demonstrate echogenicity. Multiple studies over the past two decades have demonstrated sensitivities and specificities of duplex ultrasonography exceeding 95% in *symptomatic* patients with proximal venous thrombosis.

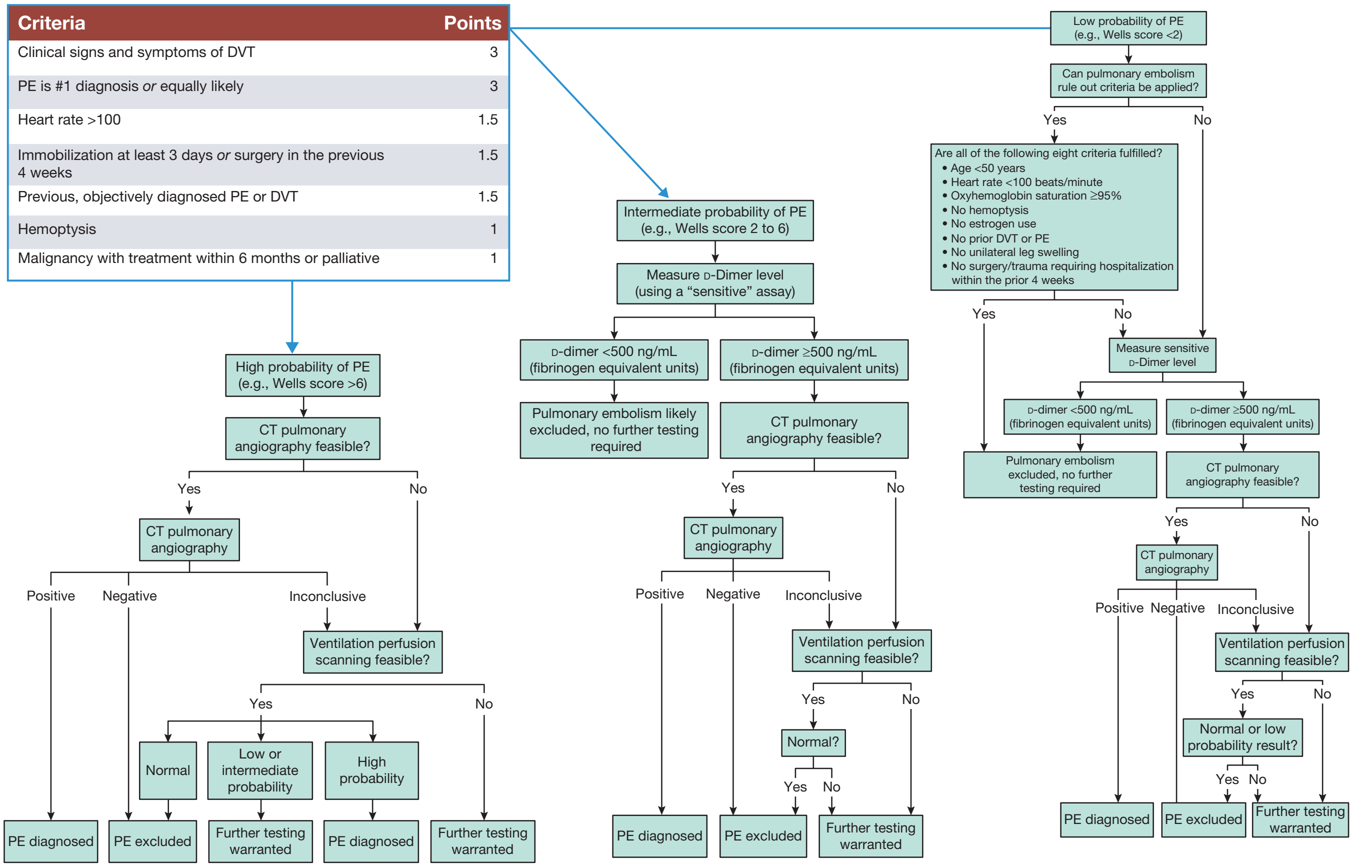
While duplex ultrasonography is highly sensitive and specific in the diagnosis of DVT in symptomatic patients, its accuracy in the diagnosis of acute PE is less clear. Approximately 40% to 50% of patients with PE will also have DVT, and the HR for all-cause mortality is 2.05 times higher for those with concomitant DVT compared to those with PE alone.[85] However, given the sensitivity of lower extremity Doppler ultrasonography of 41% with suspected PE, its use as the initial diagnostic study should be reserved for those patients with clinical evidence of DVT and for situations in which it is preferable to avoid exposure to radiation or contrast material.[86]

DIAGNOSTIC APPROACH

The diagnostic approach to PE should be targeted toward the patient population being studied (Fig. 73-11). For outpatients, the use of a clinical prediction rule coupled with D-dimer testing or the use of the PERC criteria can substantially reduce the number of imaging studies performed.[87–89]

In the outpatient setting, D-dimer results would not alter the need for an objective imaging study in patients with a high probability of PE. In patients with a low or intermediate clinical likelihood of embolism, a negative D-dimer study is sufficient to exclude the possibility of embolism, assuming a highly sensitive assay is used. An imaging study should be performed in all patients with a high probability of disease as well as those with a low or intermediate probability whose D-dimer tests are positive.

Patients with signs or symptoms of lower extremity DVT should initially undergo lower extremity duplex ultrasonography.



Criteria	Points
Clinical signs and symptoms of DVT	3
PE is #1 diagnosis *or* equally likely	3
Heart rate >100	1.5
Immobilization at least 3 days *or* surgery in the previous 4 weeks	1.5
Previous, objectively diagnosed PE or DVT	1.5
Hemoptysis	1
Malignancy with treatment within 6 months or palliative	1

High probability of PE (e.g., Wells score >6)
CT pulmonary angiography feasible?
Yes
No
CT pulmonary angiography
Positive
Negative
Inconclusive
Ventilation perfusion scanning feasible?
Yes
No
Normal
Low or intermediate probability
High probability
PE diagnosed
PE excluded
Further testing warranted
PE diagnosed
Further testing warranted
Intermediate probability of PE (e.g., Wells score 2 to 6)
Measure D-Dimer level (using a "sensitive" assay)
D-dimer <500 ng/mL (fibrinogen equivalent units)
D-dimer ≥500 ng/mL (fibrinogen equivalent units)
Pulmonary embolism likely excluded, no further testing required
CT pulmonary angiography feasible?
Yes
No
CT pulmonary angiography
Positive
Negative
Inconclusive
Ventilation perfusion scanning feasible?
Yes
No
Normal?
Yes
No
PE diagnosed
PE excluded
Further testing warranted
Low probability of PE (e.g., Wells score <2)
Can pulmonary embolism rule out criteria be applied?
Yes
No
Are all of the following eight criteria fulfilled?
• Age <50 years
• Heart rate <100 beats/minute
• Oxyhemoglobin saturation ≥95%
• No hemoptysis
• No estrogen use
• No prior DVT or PE
• No unilateral leg swelling
• No surgery/trauma requiring hospitalization within the prior 4 weeks
Yes
No
Measure sensitive D-Dimer level
D-dimer <500 ng/mL (fibrinogen equivalent units)
D-dimer ≥500 ng/mL (fibrinogen equivalent units)
Pulmonary embolism excluded, no further testing required
CT pulmonary angiography feasible?
Yes
No
CT pulmonary angiography
Positive
Negative
Inconclusive
Ventilation perfusion scanning feasible?
Yes
No
Normal or low probability result?
Yes
No
PE diagnosed
PE excluded
Further testing warranted

TABLE 73-7 Non-massive, Submassive and Massive Nomenclature for Acute PE Severity

	Incidence	Definition	Shock	sPESI >1	Imaging with RV Dysfunction	Cardiac Biomarkers	Mortality Risk
Non-Massive PE	75%	Absence of hypotension, RV dysfunction and myocardial necrosis	–	–	–	–	Low (<1%)
Submassive PE	20–25%	Systolic blood pressure >90 mm Hg and either: (1) RV dysfunction by imaging (echocardiogram or CT RV:LV ratio >1) (2) Positive biomarkers (elevated proBNP, positive troponins)	–	+	Either Positive +/–	+/–	Intermediate-Low (<5%)
			–	+	Both Positive +	+	Intermediate-High (10%)
Massive PE	<5%	Acute PE with hypotension (SBP <90 or drop greater than 40 mm Hg for longer than 15 minutes)/obstructive shock/cardiac arrest	+	+	+	+	High (>25%)

A positive lower extremity study, although not proving PE has occurred, has the same therapeutic implications. Although such an approach will yield a confirmatory study in only about 40% of embolic suspects, it avoids the cost and radiation exposure associated with CTA. A negative study is insufficient to exclude the possibility of embolism.[90]

Whatever approach is undertaken, the treating physician should be aware of the type of D-dimer assay, discriminant value of that particular assay, and generation of CT scanner used. "Negative" findings on a low-sensitivity D-dimer assay or a single-row CT scanner have very different implications than similar findings using a highly sensitive D-dimer assay or 64-MDCT scanner.

The role of D-dimer testing and clinical assessment in hospitalized patients is limited. A substantial proportion of hospitalized patients have a positive highly sensitive D-dimer result related to an active inflammatory process, malignancy, recent surgery, liver disease, and even advancing age.[91] Comorbid conditions affect the clinical likelihood assessment. Therefore, a far higher proportion of hospitalized embolic suspects require an imaging study to confirm or exclude the diagnosis.

RISK STRATIFICATION

An important element in determining treatment for patients with acute PE is determining the risk for adverse outcomes. When describing PE, there are several categories that have important implications for the risk of mortality, duration of therapy, and risk for recurrence. First among these is the distinction between massive, submassive, and nonmassive PE (Table 73-7).[7] A massive PE is a hemodynamically significant clot with obstructive shock, need for CPR, or hypotension present; this category conveys the highest short-term mortality risk. A submassive PE does not exhibit hypotension, but there are signs of right ventricular dysfunction by imaging (echocardiogram or CT with RV:LV ratio >1) and/or positive cardiac biomarkers (NT-proBNP, troponin). Patients with submassive PE are at risk for clinical deterioration and require close monitoring with consideration of advanced therapies in select populations. Finally, nonmassive PE represents the majority of PE diagnoses and convey a low risk for mortality; many of these patients can safely be treated as outpatients.[92]

A number of risk scores to predict mortality are available. The simplest to use and most widely validated is the Simplified Pulmonary Embolism Severity Index (sPESI) (Table 73-8). This score assigns a point for any of the following: age >80 years, history of cancer, chronic cardiopulmonary disease, tachycardia >110 beats per minute, systolic blood pressure <100 mm Hg, and arterial oxygen saturation <90%. If any one of these is present, the patient is deemed high risk. In the external validation of the sPESI score, 36.2% of patients were classified as low risk with a 30-day mortality of 1.1% (95% CI, 0.7–1.5) as opposed to the 63.8% of high-risk patients with a 30-day mortality of 8.9% (95% CI, 8.1–9.8).[93] The real value of this sPESI score lies in the high negative predictive rate of 98.9%. A sPESI score of zero portends that patients will do well and can be used to identify patients who can safely be managed at home.[94]

Aside from imaging, biomarkers, and risk scores, the presence of concomitant DVT should be considered in determining the risk from an acute PE. First, patients with PE and concomitant proximal DVT have a 2.02 times higher HR for PE-related death than patients with PE alone.[85] Patients with intermediate-risk PE and concomitant proximal DVT may benefit from other interventions such as suction embolectomy or IVC filter placement. Likewise, the presence of clot-in-transit (i.e., thrombus in inferior vena cava, right atrium, RV, or left atrium [if a patent foramen ovale is present]) merits consideration for potential interventions.

Most of the PE-related mortality occurs in the first 24 h after the diagnosis is made.[95] Over the past decade, there has been a movement to develop PE response teams (PERT) to rapidly risk-stratify

TABLE 73-8 Simplified PESI Score

Clinical Feature	Points
Age >80 years	1
History of cancer	1
Chronic cardiopulmonary disease	1

patients and determine whether advanced therapies such as thrombolysis, catheter-directed therapies, surgical embolectomy, or VA ECMO are warranted. These teams are typically multidisciplinary, involving pulmonologists, intensivists, cardiothoracic surgeons, and interventionalists (cardiologists and/or interventional radiologists).[96] The team quickly assembles the data, determines the risk, and then decides on an approach to management. While organization of the team and rapid decision-making in acute PE are warranted, the impact of PERT on outcomes is uncertain. Early analysis of the PERT experience demonstrates a more invasive and costly approach to the management of submassive PE with no significant improvement in mortality.[97]

APPROACH TO PE MANAGEMENT

Management of acute PE consists of a systematic approach that involves patient risk stratification, early intervention when warranted, selection of therapy, and determination of treatment duration. Only in the high-risk groups (massive and intermediate- to high-risk submassive PE) are the advanced therapies for PE considered; the nonmassive and intermediate- to low-risk submassive patients will do well with anticoagulation alone. The goals of therapy in PE are several: to assure adequate oxygenation, provide hemodynamic support, and prevent thrombus propagation and embolic recurrence. Regardless of how the patient is risk stratified, anticoagulation remains the most important initial element of the management of these patients.

There is little controversy about the management of both nonmassive and massive PE. Nonmassive pulmonary embolism is managed with anticoagulation alone, and the options for anticoagulation are discussed later. Many nonmassive patients can safely be discharged home to continue anticoagulation. Either the HESTIA score (Table 73-9) or a sPESI score of 0 can be used to identify those patients who are safe for discharge.[92] Hospitalization should be mandatory for older patients who may have less cardiopulmonary reserve or significant coexisting illnesses, or those who may not be able to follow instructions or have adequate follow-up. Other indications for hospitalization include hypoxemia or sufficient renal disease to contraindicate the use of low-molecular-weight heparin or a factor Xa inhibitor. Options for the initial phase of anticoagulation are further discussed below.

Likewise, there is little controversy related to the management massive PE. There is consensus among the societal guidelines that patients with hypotension with obstructive shock should receive thrombolytics.[7,12] The standard dose of tissue plasminogen activator (tPA) is 100 mg administered over 2 h via peripheral IV. In patients experiencing cardiac arrest, consideration can be given to bolusing tPA 50 mg followed by a 50-mg drip. These guidelines are based on one small study of massive PE with patients randomized to either tPA or standard care; patients who received tPA all survived while those treated with standard care anticoagulation alone did not all survive.[98] In those patients deemed to be too high-risk for bleeding complications with thrombolysis, surgical embolectomy or suction embolectomy are potential therapeutic options. Finally, veno-arterial extracorporeal membrane oxygenation is an option for patients with profound obstructive shock and right ventricular failure related to massive PE.

TABLE 73-9 Hestia Criteria

If any of the below are answered "Yes," the patient should NOT be treated as an outpatient.

1. Hemodynamically unstable?
2. Thrombolysis or embolectomy necessary?
3. Active bleeding or high risk of bleeding?
4. Oxygen supply to maintain oxygen >90% >24 hours?
5. Pulmonary embolism diagnosed during anticoagulant treatment?
6. In severe pain needing IV pain medication >24 hr (or multiple doses in the ED)?
7. Medical or social reason for treatment in hospital >24 hr?
8. Creatinine clearance less than 30 mL/min?
9. Severe liver impairment or disease?
10. Pregnant?
11. Documented history of heparin-induced thrombocytopenia?

In contrast to nonmassive and massive pulmonary embolism, the management of patients with submassive PE remains an area of significant controversy. While these patients clearly have a higher mortality than patients with nonmassive PE, the majority do well with anticoagulation alone. In the PEITHO trial of tenecteplase in patients with intermediate risk PE, 94.6% of patients randomized to standard-of-care anticoagulation alone did well with no further clinical deterioration.[99] Identifying those patients at highest risk for deterioration to offer advanced therapies to prevent morbidity and mortality remains an elusive target. In the past decade, several catheter-directed therapies (including those using thrombolytics delivered locally to the thrombus and devices to mechanically dislodge or disrupt the thrombus) have emerged as potential treatment options with hypothetically less risk for bleeding complications.

While the nonmassive, submassive, and massive pulmonary embolism nomenclature is based on the risk for morbidity and mortality, these should not be thought of as silos. Patients with submassive PE are at increased risk for complications and merit close attention in the first hours to days after diagnosis. The majority of these patients will do well but, should patients develop signs of clinical deterioration (i.e., hypotension, syncope, tachycardia, shock), the need for more aggressive intervention should be addressed expeditiously by a multidisciplinary team.

OPTIONS FOR INITIAL TREATMENT

A variety of options can be considered for initial treatment.

■ Heparin

Anticoagulation with heparin remains the standard initial therapy for hospitalized patients. The major anticoagulant effect of heparin is to reduce thrombus propagation and prevent embolic recurrence. Choices include either intravenous unfractionated heparin (UFH) or subcutaneous low-molecular-weight heparin (LMWH) preparations. Given that failure to achieve rapid therapeutic levels of anticoagulation appears to be associated with an increased recurrence rate, it is important to ensure adequate anticoagulation as soon as possible.[100]

Physician practices in the administration of intravenous UFH have often resulted in substantial delays before adequate prolongation of the activated partial thromboplastin time (aPTT) is achieved. To overcome these problems, standardized protocols for heparin administration and monitoring have been recommended. One commonly employed dosing regimen using an initial IV bolus of 80 units of heparin per kilogram followed by a continuous infusion initiated at 18 units per kilogram per hour has been demonstrated to reach therapeutic thresholds more quickly than regimens using fixed dosing.[101] The heparin drip is adjusted based on monitoring of the activated partial thromboplastin time (aPTT), drawn 6 h after the initial bolus dose, then 6 h after each dose adjustment, with a target aPTT ratio of 1.5 to 2.5. Because attempts to straddle the lower therapeutic range may result in periods of inadequate anticoagulation, it is prudent to maintain the ratio in the upper range of the recommended target. Although more costly than aPTT, many centers have adopted heparin protocols targeting anti-Xa levels. The anti-Xa level is a more accurate direct measure of heparin activity against activated factor X and is unaffected by the baseline PTT (which can be prolonged in cases such as those with antiphospholipid antibodies). The anti-Xa level can be falsely low in the setting of antithrombin III deficiency.[102]

The major advantages of intravenous UFH are that it can be bolused to rapidly achieve a therapeutic window and can be shut off if there is a need for thrombolysis or bleeding complications develop. While there is disagreement between American and European guidelines on the matter, most would recommend stopping heparin infusion prior to administering thrombolytics and restarting therapeutic anticoagulation with heparin drip after the infusion is completed.

With the exception of special circumstances, LMWH preparations have displaced UFH as the anticoagulant of choice in uncomplicated VTE, as the incidence of recurrent thromboembolic events was found to be lower in those treated with LMWH than in those treated with UFH.[103] Situations in which the use of UFH is still appropriate include renal insufficiency; extremes of body weight; and circumstances in which a rapid adjustment or reversal of anticoagulation is needed, such as women in the late stage of pregnancy who may need cesarean sections, patients with recent surgery or recent history of bleeding, and hemodynamically unstable patients with VTE who may need surgical procedures such as emergency embolectomy.

Available evidence suggests that LMWH is at least as effective as UFH in treating acute PE. Advantages of LMWH compared with UFH include (1) longer half-life and ease of use; (2) ability to consistently achieve early therapeutic anticoagulation; (3) no need to monitor anticoagulant effects; and (4) reduced incidence of major bleeding complications. Even though there are differences in the FDA-approved indications for different LMWH preparations in the United States, it is not clear that their actions differ significantly.

In general, therapeutic monitoring is not needed with LMWH, but there are situations where the therapeutic effects may be less predictable and monitoring with anti-Xa levels is indicated. These include (1) patients with antiphospholipid antibodies or other circulating anticoagulants leading to elevated baseline aPTT; (2) extremes of body weight (<40 kg and >150 kg); (3) creatinine clearance <30 mL/min; (4) pregnancy; and (5) unexplained bleeding or recurrent thrombosis during therapy. A therapeutic target range for peak anti-Xa levels ranges from 0.6 to 1.0 IU/mL, measured 4 h after administration. The target range for peak anti-Xa levels with once daily enoxaparin is >1.0 IU/mL whereas it is >0.85 IU/mL with tinzaparin and 1.3 IU/mL and 1.05 IU/mL with nadroparin and dalteparin, respectively.[104]

Intravenously administered direct thrombin inhibitors (lepirudin, argatroban) represent another class of anticoagulant agents that have been approved for the management of patients with PE in the setting of heparin induced thrombocytopenia (HIT).[105] Their mechanism of action differs from that of heparin and the synthetic pentasaccharides in that they directly inhibit the active site of thrombin and do not require interaction with antithrombin to produce an anticoagulant effect. Argatroban is a synthetic agent derived from arginine. It has a half-life of approximately 45 min and is cleared by the liver. Lepirudin is a recombinant polypeptide similar to hirudin. It has a half-life of 40 to 60 min and is cleared by the kidneys. Both agents are administered by continuous IV infusion and dose adjustments made with monitoring of the aPTT. Both agents affect the international normalized ratio (INR), thereby complicating the transition to oral warfarin therapy.

■ Thrombolytic Therapy

Unlike anticoagulants, thrombolytic drugs cause direct lysis of thrombi by increasing plasmin production through plasminogen activation. The use of thrombolytics is considered in patients with cardiopulmonary compromise, as these agents rapidly lyse the emboli causing obstructive shock. However, the potential benefits are often offset by the relatively high incidence of hemorrhagic complications. Proper patient selection and dosing are key to the safe use of these agents.

Multiple thrombolytic agents are available. Those most studied for the management of acute PE include streptokinase, alteplase (rt-PA), urokinase, and tenecteplase, all of which are FDA-approved for use in the United States. The exact role of thrombolytic agents in acute PE remains controversial. While thrombolytic therapy does appear to accelerate the rate of thrombolysis, there are no high-quality data to show that thrombolysis decreases mortality in submassive PE.[106] The one issue about which there can be little controversy is that the use of thrombolytic agents is associated with a substantially increased risk of bleeding, including intracranial hemorrhage. The absolute and relative contraindications are listed in Table 73-9. Compared with anticoagulation alone, the risks for both major bleeding (9.24% vs. 3.42%) and intracranial hemorrhage (1.46% vs. 0.19%) are increased in patients receiving thrombolytics, although this risk is not elevated in those <65 years of age.[107]

Based on these data, and assuming there is no contraindication to its use, the use of thrombolytic therapy for PE appears to be appropriate when an accelerated rate of thrombolysis is considered to be potentially lifesaving—that is, in patients with PE who present with hemodynamic compromise in whom the mortality rate approaches 30%. The role of thrombolytic therapy in patients with anatomically massive embolism or echocardiographic evidence of right ventricular dysfunction in the absence of systemic hypotension has been thoroughly studied but remains poorly defined. In the PEITHO trial, 1006 patients with intermediate-risk PE (normotensive patients with both RV dysfunction by imaging and evidence of elevated cardiac biomarkers) were randomized to either tenecteplase plus heparin or placebo plus heparin.[99] While the study met its primary endpoint of reducing the combined rate of death and hemodynamic collapse (2.6% in the tenecteplase group vs. 5.6% in the placebo group; $p = 0.02$), this came at the expense of increased risk for hemorrhage (6.3% with tenecteplase vs. 1.2% with placebo; $p < 0.001$) and stroke (2.4% vs. 0.2%; $p = 0.003$). The improvement in the combined endpoint was driven not by an improvement in mortality but rather a reduction in hemodynamic decompensation (1.6% vs. 5.0%; $p = 0.002$). These data provide reassurance that the majority of these submassive, intermediate-high risk patients will do well with anticoagulation alone, but they require careful monitoring for deterioration, which occurred in about 1 in 20 patients.

Some have advocated using lower doses of thrombolytic to reduce the risk of bleeding complications. There is even less evidence to support this approach. In the MOPPET study, a lower dose of tPA, 50 mg, was compared to standard of care for patients with a nonstandard definition of moderate PE (based on radiographic size of the thrombus and clinical signs of disease burden).[108] Methodologic flaws, single-center design, and the poorly chosen endpoint of echocardiographic evidence of pulmonary hypertension at 6 months with extraordinarily high rates of pulmonary hypertension seen in both groups severely limit the interpretation and generalizability of this study. Additional data derived from multicenter, randomized controlled trials is needed before lower-dose peripheral thrombolytics can be recommended.

■ Catheter-Directed Therapy

Over the past decade, a number of intravascular catheters have been developed to treat submassive PE (Fig. 73-12).[109] These catheters are utilized for either catheter-directed thrombolysis or suction embolectomy. These catheter-based approaches may offer more rapid recovery and are associated with lower bleeding risks compared with systemic thrombolysis.[110]

The rationale for catheter-directed thrombolysis is that by delivering the thrombolytic into or in close proximity to the thrombus, higher

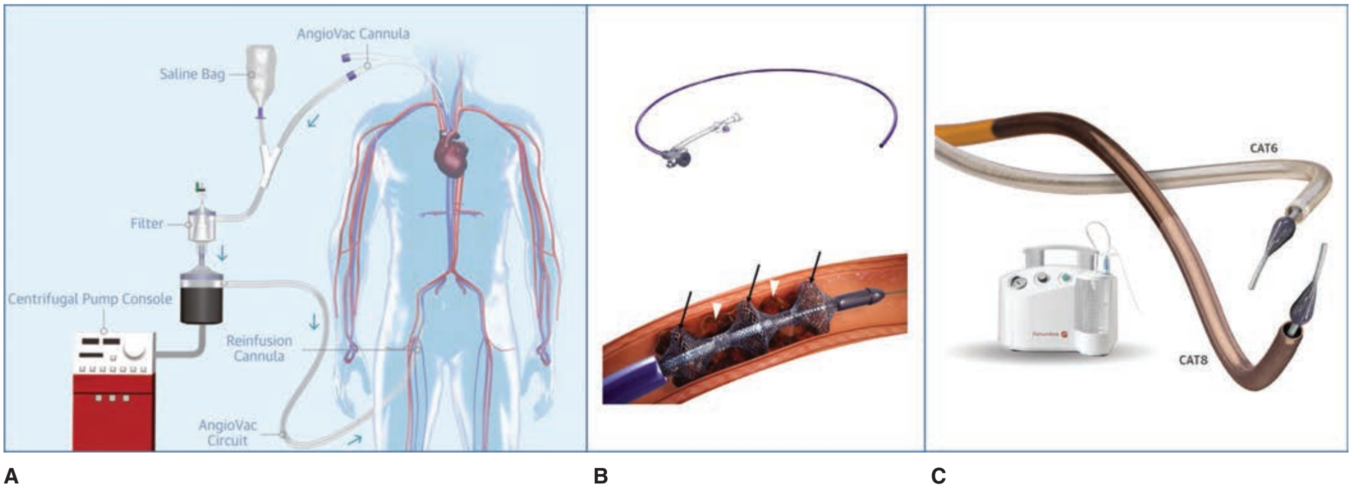

Figure 73-12 Examples of available suction embolectomy catheters. **A.** The AngioVac system is a large-bore (26-F) aspiration catheter requiring a centrifugal pump and return cannula. **B.** The FlowTriever system uses a 22-F aspiration guide catheter with syringe for suction and a catheter with nitinol discs for mechanical disruption of thrombus. **C.** The Penumbra aspiration system uses a smaller-bore catheter (6- to 8-F) with separator wires for mechanical disruption of thrombus and uses an automated aspiration system. *(Reproduced with permission from Jaber WA, Fong PP, Weisz G, et al. Acute Pulmonary Embolism: With an Emphasis on an Interventional Approach. J Am Coll Cardiol. 2016;67(8):991–1002.)*

local concentrations can be achieved with lower total doses of the lytic. Many catheters mechanically fragment the thrombus or provide ultrasonic vibration that theoretically enables the lytic to permeate into the thrombus. It is not clear that catheter-directed thrombolysis mitigates the systemic lytic effect as seen with IV administration; since the half-life of tPA is 4 min, the effect of recirculation of tPA is 5 times greater than the effect of the first pass. Indeed, the risk of bleeding with catheter-directed thrombolysis in the SEATTLE-II trial was similar to that of systemic tenecteplase in the PEITHO trial.[99,111] Additionally, there is no demonstrable benefit to the addition of ultrasound assistance in the resolution of clot. In a study of iliofemoral DVT treated with catheter-directed thrombolysis regimen, the addition of intravascular ultrasound did not accelerate thrombus resolution.[112]

The data to support the use of catheter-directed thrombolysis come mainly from three studies, only one of which was randomized and controlled. The ULTIMA study randomized patients with submassive PE to either ultrasound assisted, catheter-directed thrombolysis or standard anticoagulation to assess a change in RV:LV ratio at 24 h.[113] Patients treated with the catheters achieved significant improvement in mean RV/LV ratio, which was reduced from 1.28 ± 0.19 at baseline to 0.99 ± 0.17 at 24 h ($p < 0.001$); patients in the heparin arm had no significant difference in RV:LV size at 24 h. In the prospective, single-arm SEATTLE-II study of patients with PE treated with ultrasound-facilitated, catheter-directed, low-dose fibrinolysis, similar improvement in RV:LV ratio at 24 h was seen but this came at the expense of moderate bleeding complications in 10% of patients.[111] The PERFECT trial was a single-arm safety study with no major procedure-related complications, major bleeding, or hemorrhagic strokes.[114] No study of catheter-directed therapy to date has shown a mortality benefit or any evidence of reduction in the long-term morbidity from PE.

A more recent advance in catheter-directed therapy is the emergence of suction embolectomy and mechanical thrombectomy catheters. There are a number of FDA-approved devices that are now available, and these have the main benefit of avoiding thrombolytics and thus have less risk for bleeding complications than catheter-directed thrombolysis. In the FLARE study of the FlowTriever suction embolectomy catheter (Inari Medical), similar improvements in RV:LV ratio were seen compared to those from catheter-directed thrombolysis, but there were fewer bleeding events (0.9% with major bleeding, all at catheter insertion sites) and shorter median length of stay.[115] The EXTRACT-PE study with the aspiration system from Penumbra achieved a significant reduction in RV/LV ratio at 48 h with similar low rates of bleeding complications.[116] There are several options for mechanical thrombectomy including the Amplatz thrombectomy catheter and the AngioJet Catheter, which both use proprietary mechanisms to fragment the embolic material and then create a vacuum to aspirate it. Rheolytic embolectomy with the Angiojet catheter was associated with a higher incidence of bradycardia, hemolysis, and procedure-related deaths in a meta-analysis, which resulted in a Black Box warning for this device in acute PE.[117] The AngioVac system can be considered for clot in transit in the right atrium or ventricle. The device incorporates extracorporeal bypass to return the blood removed after the clot is filtered out; about 25% of patients will require transfusion with an average drop in hemoglobin of 1 gram/dL.[118]

The role of catheter-directed therapy remains in flux. None of the major societal guidelines support the routine use of these devices in patients with submassive PE. As experience with the devices increases, the safety of the intervention as well as improved patient selection may expand their use. However, large randomized controlled trials comparing these interventions to the standard of care of heparin anticoagulation are needed before widespread use of these devices is recommended.

■ Vena Cava Interruption and Vena Cava Filter

The concept of vena cava interruption came from the historic practice of surgical ligation (by complete vascular ligation or partial interruption using surgical suture) of the inferior vena cava (IVC) in an attempt to prevent thrombus migration. A variety of IVC filters are now available including both permanent and temporary (removable as well as biodegradable) options (Fig. 73-13).

The central indication for IVC filter placement is to prevent PE in patients with VTE who have a contraindication to anticoagulation. Recent data suggest that the utilization of IVC filters has expanded since their introduction and that IVC filters are being placed for alternative reasons, including prophylaxis.[119] Much of this expansion in utilization can be attributed to the development of retrievable IVC filters which, in many instances, are never removed.[120] Guidelines for filter placement, albeit based on limited data, have been established by the American College of Chest Physicians (ACCP) and the Society of Interventional Radiologists (SIR).[12,121] These recommendations are somewhat disparate, with the SIR recommendations being considerably more liberal than those of the ACCP.

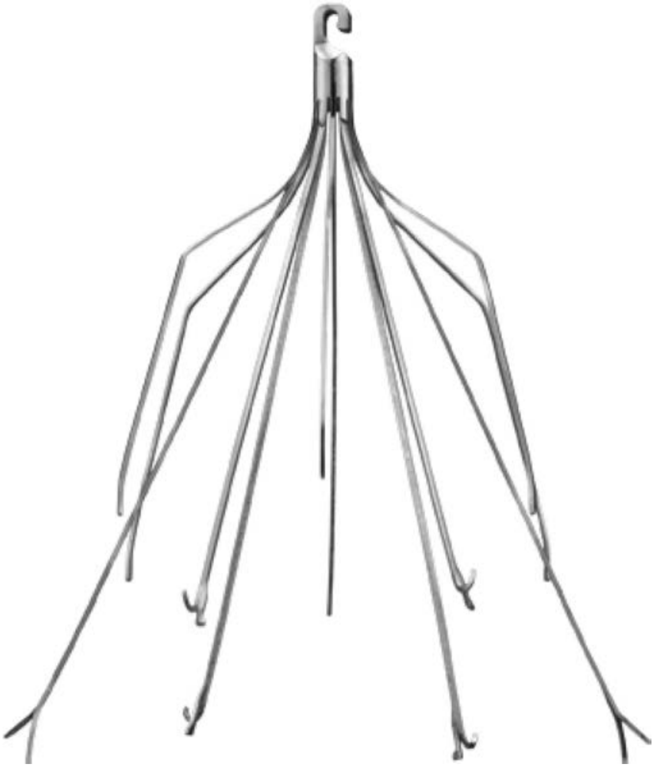

Figure 73-13 Example of retrievable inferior vena cava filter. The Denali retrievable IVC filter by BD. There are similar retrievable filters from other manufacturers.

Retrospective analysis of registry data has suggested a mortality benefit with IVC filter insertion in acute PE.[122] Randomized controlled trials have evaluated filter efficacy in several situations. In the PREPIC trial, 400 patients with proximal DVT were randomly assigned to either standard anticoagulation alone or anticoagulation plus insertion of a Vena Tech, Greenfield, Bird's Nest, or Cardial IVC filter.[123] During the first 12 days after randomization, significantly fewer patients in the IVC filter group suffered PE (1% vs. 5%). However, after a 2-year follow-up period, there were no significant differences in survival or symptomatic PE between the two groups, and a significantly higher rate of recurrent DVT was observed among patients who had received an IVC filter (21% vs. 12%).[124]

Patients with concomitant PE and DVT clearly represent a higher-risk population with HR for death about 2.05 times higher than those with PE alone.[85] The PREPIC-2 trial sought to determine the role of retrievable IVC filters in this patient population.[125] Patients with acute PE and deep or superficial vein thrombosis were included if they had one of the following risk factors: age >75 years, chronic heart failure, chronic respiratory insufficiency, active cancer, RV dysfunction or myocardial injury, recent stroke with leg paralysis, or bilateral deep vein or iliocaval thrombosis. The majority of patients were included based on age or comorbidity rather than the higher-risk groups of RV dysfunction or more proximal DVT. The deployment of a retrievable IVC filter did not reduce the risk of recurrent PE when compared with anticoagulation alone in this study. The rationale for considering use of IVC filters in those with intermediate-risk PE and concomitant DVT (especially those with more proximal DVT) remains unanswered by the PREPIC-2 study.

Placement of an IVC filter is not a benign procedure and carries several possible risks including potential DVT formation, filter migration, filter tilt, filter thrombosis, and the possibility of a higher incidence of lower extremity thrombotic events and postthrombotic syndrome.[126] Furthermore, as retrievable filters replace the permanent filters, attention should be given to the removal of the filter after 3 to 6 months of therapy. Despite the use of retrievable IVC filters, Medicare claims data demonstrate that only about 14% were removed.[127]

LONG-TERM MANAGEMENT

Long-term management centers on use of a variety of anticoagulants and antiplatelet agents, as discussed below.

Direct Oral Anticoagulants

In the past decade, the direct oral anticoagulants (DOACs) have altered the treatment paradigm for acute PE. There are four drugs that have been approved for the management of venous thromboembolism in this class: apixaban, rivaroxaban, edoxaban, and dabigatran[128] (Table 73-10). The first three are Xa inhibitors, while dabigatran is a direct thrombin inhibitor. All four were individually

TABLE 73-10 Summary of the Direct Oral Anticoagulants Approved for Management of Pulmonary Embolism

	Apixaban	Rivaroxaban	Edoxaban	Dabigatran
Mechanism of Action	Factor Xa inhibitor	Factor Xa inhibitor	Factor Xa inhibitor	Direct Thrombin Inhibitor
Acute VTE Dosing	10 mg BID × 7 days then 5 mg BID	15 mg BID × 21 days then 20 mg daily	60 mg daily	150 mg BID
Parenteral Therapy Required at Initiation	No	No	5–10 days of parenteral therapy	5–10 days of parenteral therapy
Extended Therapy Dosing (after initial 6 months of therapy)	Option to reduce to 2.5 mg BID	Option to reduce to 10 mg daily	No data on dose reduction	No data on dose reduction
Study Name	*AMPLIFY*	*EINSTIEN-PE*	*HOKUSAI-VTE*	*RECOVER*
VTE Recurrence Rate	2.3% (vs. 2.7% with warfarin)	2.1% (vs. 1.8% with warfarin)	3.2% (vs. 3.5% with warfarin)	2.4% (vs. 2.1% with warfarin)
Major Bleeding Rate	0.6% (vs. 1.8% with warfarin)	1.1% (vs. 2.2% with warfarin)	8.5% (vs. 10.3% with warfarin)	1.6% (vs. 1.9% with warfarin)
Renal Considerations	Avoid if CrCl <15 mL/min	Avoid if CrCl <30 mL/min	Avoid if CrCl <15 mL/min	Avoid if CrCl <30 mL/min
Special Consideration		Must be taken with food		Avoid if dyspepsia/GI symptoms present

compared to warfarin in efficacy for treatment of VTE and were all noninferior; in those same trials, the DOACs were all associated with less relevant bleeding than warfarin.[129–134] The DOACs do not require monitoring and all now have widely available reversal agents: andexanet alfa for the Xa inhibitors and idarucizumab for dabigatran.[135,136]

Edoxaban and dabigatran require parenteral lead-in with at least 5 to 10 days of either heparin drip or LMWH subcutaneously.[132,133] Apixaban and rivaroxaban do not require parenteral lead-in but do require dose escalation during the initial treatment period.[129,131] In patients with low sPESI scores and no contraindication to early discharge, the ease of use for both apixaban and rivaroxaban, as well as the excellent associated outcomes, have led to more patients being discharged early from the emergency department.

Apixaban and rivaroxaban have been used successfully for extended therapy after the first 6 months of treatment in patients with PE. With either drug, there is an option for reducing the dose after the first 6 months of therapy. Extended thromboprophylaxis with apixaban 2.5 mg twice daily was evaluated in the AMPLIFY-EXT trial; compared to placebo, treatment with apixaban 2.5 mg resulted in significantly fewer recurrent venous thromboemboli (1.7% vs. 8.8%, a difference of 7.2 percentage points; 95% CI, 5.0–9.3) with no significant increase in bleeding (0.5% in the placebo group; 0.2% in the apixaban group).[137] Compared to extended treatment with full-dose rivaroxaban 20 mg or aspirin 81 mg, there was less recurrent VTE among those on rivaroxaban (1.5% with 20 mg of rivaroxaban and 1.2% with 10 mg of rivaroxaban) compared with 4.4% receiving aspirin alone. The risk of major bleeding was similar among all three groups.[138]

■ Warfarin

Oral anticoagulation using warfarin, a vitamin K antagonist, has historically been used for long-term treatment of VTE because of its proven efficacy, but it has largely been replaced by the DOACs in the past decade. Still, there are many patients for whom warfarin is used including those with antiphospholipid antibodies, recurrent thrombosis, and mechanical valves and those in whom the cost of the DOACs precludes their use. Warfarin has a broader anticoagulation effect due to inhibition of gamma carboxylation activation of coagulation factors II, VII, IX, and X as well as proteins C and S. The drug is usually started soon after the initiation of heparin therapy. Use of warfarin without heparin is strongly discouraged as it generally takes 3 to 5 days of warfarin administration to achieve full therapeutic efficacy. In patients with protein C deficiency, skin necrosis or paradoxical thrombosis may occur in the absence of concurrent heparin therapy.

Warfarin has a narrow therapeutic index, and patients are generally monitored closely by measuring the prothrombin time corrected to the reagent being used (the International Normalized Ratio or INR). To maximize efficacy while minimizing side effects, an INR range between 2 and 3 is recommended for most patients. Individuals metabolize warfarin differently, and age, genetic variations in CYP2C9 alleles, nutritional factors, and concomitant medications can affect anticoagulant levels significantly. Multiple mechanisms of drug interaction are possible, including alterations of absorption (cholestyramine), induction of hepatic CYP450 (barbiturates, carbamazepine), inhibition of CYP3A4 (amiodarone), inhibition of CYP2C9 (metronidazole, clotrimazole), and displacement of protein-bound warfarin (phenytoin).[139]

To minimize the potential for subtherapeutic anticoagulation, it is generally recommended that patients should receive at least 5 days of combined heparin and warfarin therapy, including at least 2 days in which the INR is in a therapeutic range prior to stopping heparin. The safety and effectiveness of both short- and long-term anticoagulation can be optimized by a systematic, evidence-based approach to therapy, often in the context of a dedicated anticoagulation management service.[140] In carefully selected patients, self-management of warfarin therapy using INR measurement with "point of care" devices is an option.[121]

■ Heparin

LMWH and subcutaneous UFH continue to have a role in the management of select patients after PE such as those who cannot take oral medications, pregnant women, those with need for frequent procedures who benefit from the short half-life, and certain patients with cancer-associated VTE. Compared with vitamin K antagonists, LMWH has similar rates of VTE recurrence (OR, 0.83; 95% CI, 0.60–1.15; $p = 0.27$) but less risk for major bleeding (OR, 0.51; 95% CI, 0.32–0.80; $p = 0.004$).[141] Enoxaparin is the most prescribed LMWH in the United States and can be given either 1 mg/kg twice per day or 1.5 mg/kg daily. In a large, retrospective propensity analysis of the RIETE registry, patients on enoxaparin once daily had fewer major bleeds (HR, 0.16; 95% CI, 0.04–0.68) and also fewer deaths at 30 days (HR, 0.19; 95% CI, 0.07–0.54) compared with those on enoxaparin twice daily.[142] Aside from risk of bleeding, prolonged use of subcutaneous UFH or, to a lesser extent, LMWH, is associated with increased risk of osteoporosis.[143]

■ Aspirin

The role of aspirin in the long-term management of patients with VTE remains incompletely defined. In the WARFASA (Warfarin and Aspirin) trial, aspirin reduced the risk of thromboembolic recurrence by 40% when given to patients with unprovoked VTE following discontinuation of anticoagulant therapy.[144] In the ASPIRE (Aspirin to Prevent Recurrent Venous Thromboembolism) trial, however, aspirin compared with placebo did not significantly reduce the rate of recurrence of VTE but resulted in a significant reduction in the rate of major vascular events, with improved net clinical benefit.[145] The use of aspirin has further been obfuscated by recent shift away from primary prophylaxis for cardiovascular events due to excessive risk for bleeding.[146] Ultimately, we recommend that patients with unprovoked PE but low risk for major bleeding complications remain on indefinite anticoagulation; if the patient declines, we would consider using aspirin 81 mg in those patients without a contraindication.

FOLLOW-UP AFTER ACUTE PE

The most common long-term sequelae of an acute PE are recurrent embolism and incomplete resolution of clot. More than 50% of patients develop or have worsening dyspnea after PE.[50] Patient symptoms may vary in degree, ranging from mild dyspnea due to dead space ventilation, to severe functional limitation as a result of chronic thromboembolic pulmonary hypertension (CTEPH). Therefore, the follow-up visit after the initial 3 months of anticoagulation for PE provides an opportunity to assess the risks and benefits of extended anticoagulation and to evaluate the etiology of dyspnea for those patients who have not yet returned to their pre-PE baseline.

■ Duration of Therapy

Over the past decade, data have emerged that have significantly changed recommendations regarding duration of anticoagulation after VTE. Central to this change has been awareness that VTE often represents a recurrent disease and that the risk for recurrence is based on the initiating factors, persistence or resolution of those factors, and anatomic consequences of the initial event.

Patients with VTE associated with a transient risk factor appear to be at a low risk of recurrence. Patients who experience postoperative VTE are at especially low risk for recurrence. Three months of anticoagulation appears to be adequate in this group, assuming

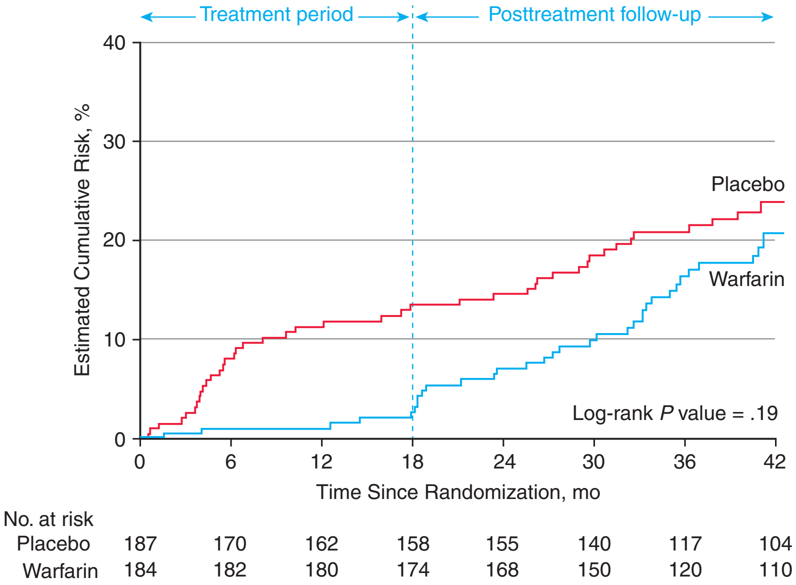

Figure 73-14 PADIS-PE Study demonstrates high long-term risk for recurrent VTE after unprovoked initial VTE if anticoagulation stopped.

The unadjusted hazard ratios for warfarin-placebo were 0.23 (95% CI, 0.09-0.55) during the treatment period and 0.74 (95% CI, 0.47-1.17) for the entire study period. The y axis that is shown in blue indicates the range of estimated cumulative risk from 0% to 10%.

the risk factor has resolved. Patients with idiopathic (unprovoked) VTE have a substantially higher rate of recurrence, corresponding to an annualized event rate of 7.9% per patient-year.[147] For these patients, anticoagulation may simply delay subsequent recurrent thromboembolic events, and ongoing risk factors may be present that have yet to be identified. In the PADIS-PE trial of extended anticoagulation with warfarin in patients with unprovoked PE, prolonged anticoagulation to 24 months was associated with a lower rate of VTE recurrence compared with 6 months of anticoagulation; this effect was lost after anticoagulation was stopped at 24 months with no difference in the rate of VTE recurrence between the two groups at 3.5 years (Fig. 73-14).[148] Therefore, it is recommended that strong consideration be given to extended therapy in those patients with unprovoked VTE and a low/moderate risk of bleeding complications.[129]

While decisions regarding extended anticoagulation can often be made based on the provoked or unprovoked nature of the VTE, there are several validated tools that are available for granular quantification of VTE recurrence risk should anticoagulation be discontinued (Table 73-11). The HERDOO2 rule identifies adult women

TABLE 73-11 Risk Assessment Tools for Unprovoked VTE Recurrence After Cessation of Anticoagulation

Risk Assessment Tool	Factors	Points	Total Score	Annual Risk of Recurrence
HERDOO2	Post-thrombotic signs	1	0–4	Men: 8.4–13.7%
	D-dimer level 250 μg/L	1		Women with score <2: 1.6–3.0%
	BMI 30 kg/m^2	1		Women with score 2: 7.4–14.1%
	Age ≥65 years	1		
DASH	D-dimer level abnormal at 1 month post-anticoagulation discontinuation	2	−2 to 4	Score 1: 0.5–5.3%
				Score 2: 6.4–6.7%
	Age 50 years	1		Score 3: 6.8–12.3%
	Male	1		
	Hormone use at VTE onset	−2		
Vienna Prediction Model	Sex	NA	0–350	2–15%, depending on nomogram-based score
	Location of VTE	NA		
	D-dimer level elevated at 3 weeks post-anticoagulation discontinuation	NA		
Ottawa	Female sex	1	−3 to 3	Score <0: 2.4–4.5%[a]
	Prior VTE	1		Score 0: 4.5–8.8%[a]
	Primary lung cancer	1		Score ≥1: 15.9–19%[a]
	Primary breast cancer	−1		
	Tumor stage (TNM 1)	−2		

[a] *Risk of recurrent VTE at 3–6 months.*

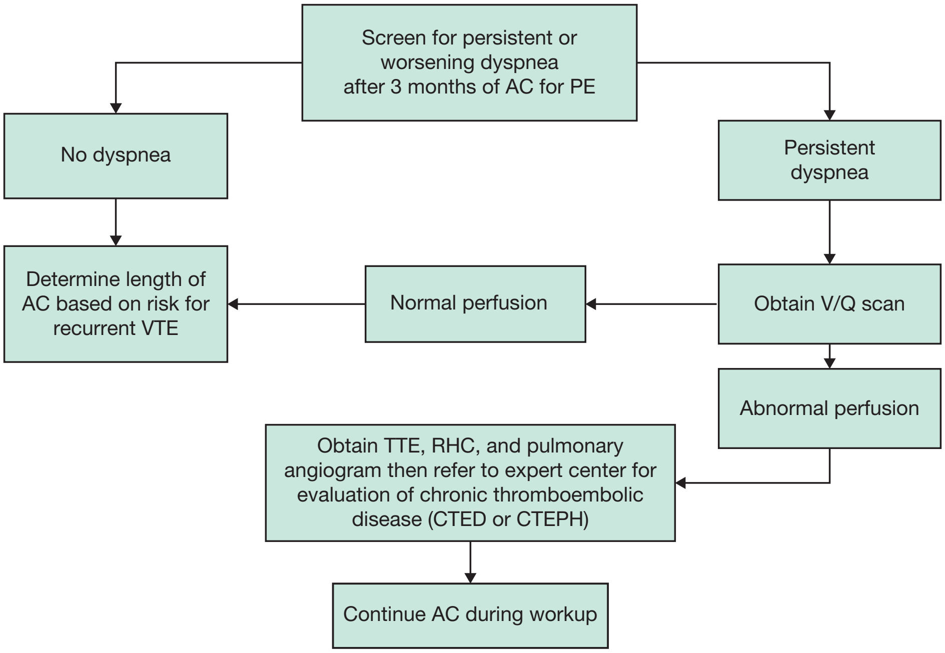
with prior unprovoked VTE who have an annual risk of VTE of less than 3% and can, therefore, safely discontinue anticoagulant therapy.[149] According to the HERDOO2 rule, women with 0 or 1 of the following risk factors can safely discontinue anticoagulation: postthrombotic signs (e.g., hyperpigmentation, edema, redness in either leg), elevated D-dimer on anticoagulation, BMI of 30 kg/m^2 or greater, or age 65 years or greater. Similarly, the DASH prediction score identifies patients at risk for recurrent VTE based on elevated D-dimer levels 1 month post-anticoagulation discontinuation, age, sex, and hormone use at VTE onset.[150] The Vienna Prediction Model evaluates VTE risk recurrence on a spectrum based on sex, location of VTE, and elevated D-dimer 3 weeks after anticoagulant discontinuation.[151] Finally, the Ottawa score assesses risk for recurrent cancer-associated VTE and considers sex, cancer type and stage, and prior VTE.[152] The HERDOO2, DASH, and Ottawa prediction models provide discrete risk categories, whereas the Vienna prediction model gives a continuum of annualized risk, which may be a more accurate portrayal of the nuances of recurrence risk. Both the DASH and Vienna models evaluate D-dimer levels after discontinuation, but discontinuation of therapy may not be wise for some patients. The HERDOO2 model is the only tool that considers D-dimer levels in anticoagulation and does not require discontinuation of therapy.

In patients with VTE associated with an irreversible risk factor, the absolute recurrence risk depends on the underlying disease or condition.[131,132] Patients with heterozygous factor V Leiden mutation and the prothrombin G20210A mutation, although at higher recurrence risk than those without the mutations, do not appear to warrant prolonged anticoagulation while those with homozygous disease or a combined thrombophilia (e.g., heterozygous factor V Leiden combined with heterozygous prothrombin mutation) do. Patients with antiphospholipid antibody syndrome, active cancer, and deficiencies of protein S, protein C, and antithrombin III (ATIII) are at considerable risk for thromboembolic recurrence and should remain on lifelong therapy. In summary, long-term anticoagulation should be individualized based on the risk for recurrent thromboembolism and bleeding. The appropriateness of ongoing therapy should be continuously reevaluated, and the prophylaxis stopped if the benefit no longer appears to exceed the risk.

Assessment of Recovery from the Initial PE

The expectation is that, with adequate anticoagulation, patients will recover fully to their pre-PE baseline. However, the reality is that approximately 50% of patients report worsening dyspnea compared with their pre-PE baseline after 6 months of anticoagulation.[153] Additionally, some 30% to 50% of patients will have an abnormal perfusion scan after 6 months of anticoagulation.[49,50] Determining whether the dyspnea experienced by these patients is due to persistent perfusion defects requires assessment with cardiopulmonary exercise testing and echocardiography. Patients with dyspnea after at least 3 months of anticoagulation should be evaluated for thrombus resolution and a ventilation–perfusion scan should be obtained (Fig. 73-15). Screening echocardiography in all patients after PE to exclude CTEPH is very low yield and not recommended,[154] but echocardiograms should be obtained in patients with dyspnea and/or persistent perfusion defects to screen for resting pulmonary hypertension. Some centers use noninvasive cardiopulmonary exercise testing to quantify dead space ventilation and assess the stroke volume response to exercise.[155] If significant perfusion defects are seen, pulmonary angiography should be obtained to confirm the diagnosis of chronic thromboembolic disease.

Early diagnosis and treatment of CTEPH is essential for optimal patient outcomes. A number of factors pertaining to the acute PE and comorbidities have been identified and increase the risk for development of CTEPH after acute PE (Table 73-12), specifically having an unprovoked PE, hypothyroidism, a delay in PE diagnosis >2 weeks, or right ventricular dysfunction on CT angiography at the time of the acute PE.[156] Patients with recurrent PE also have higher odds for development of CTEPH (OR, 3.2; 95% CI, 1.7–5.9).[157] Patients with these risk factors merit close follow-up and screening to assess resolution of dyspnea. In patients without dyspnea who have returned to their pre-PE baseline, routine screening for CTEPH is not recommended after PE. However, the 2019



Screen for persistent or worsening dyspnea after 3 months of AC for PE
No dyspnea
Persistent dyspnea
Determine length of AC based on risk for recurrent VTE
Normal perfusion
Obtain V/Q scan
Abnormal perfusion
Obtain TTE, RHC, and pulmonary angiogram then refer to expert center for evaluation of chronic thromboembolic disease (CTED or CTEPH)
Continue AC during workup

Figure 73-15 Recommended evaluation of dyspnea post-PE. AC = anticoagulant; CTED = chronic thromboembolic disease; CTEPH = chronic thromboembolic pulmonary hypertension; PE = pulmonary embolism; RHC = right heart catheterization; TTE = transthoracic echocardiogram; V/Q = ventilation/perfusion; VTE = venous thromboembolism.

TABLE 73-12 Selected Risk Factors and Univariate Odds Ratios for CTEPH

Risk Factor	Comparator	OR (95% CI)
VA shunt	IPAH	19.49 (2.47–2520)
Splenectomy	IPAH	22.09 (2.97–2824)
Massive/submassive PE	IPAH	13.03 ($p = .004$)[a]
VTE history	IPAH	49.01 ($p < .001$)[a]
Recurrent VTE	IPAH	45.02
Thyroid replacement	IPAH	(21.00–114.73) 5.41 (2.70–12.23)
Hypothyroidism	Resolved PE	4.3 (1.4–13.0)
Prior VTE	IPAH	19.36 (11.66–33.79)
APS/lupus AC	IPAH	3.28 (1.58–7.50)
Non-blood group O	IPAH	3.12 ($p < .001$)[a]
Malignancy	IPAH	1.99 (1.01–4.26)
Unprovoked PE	Resolved PE	20.0 (2.7– >100)
RV dysfunction at diagnosis	Resolved PE	4.1 (1.4–12.0)
Symptoms >2 weeks prior to PE diagnosis	Resolved PE	7.9 (3.3–19.0)
Age >60 years	Resolved PE	2.9 (1.2–7.2)

[a] *Adjusted for age and sex.*

ESC/ERS guidelines do recommend consideration of CTEPH in PE survivors with exercise dyspnea.[7] Evaluation for CTEPH should be based on clinical suspicion due to persistent symptoms or dyspnea following at least 3 months of adequate anticoagulation therapy.

SPECIAL POPULATIONS

Several populations of patients with VTE merit special mention, including pregnant women, patients with underlying malignancy, and those with chronic thromboembolic disease.

Pregnancy

VTE is a leading cause of maternal morbidity and mortality during pregnancy but remains a diagnostic and therapeutic challenge.[158] The mechanical compression of the pelvic veins by the gravid uterus and the hormonal milieu of pregnancy and the puerperium period increase the risk for VTE above baseline. However, dyspnea and lower extremity edema are common in pregnancy, and the typical screening algorithms dependent on use of the D-dimer test are not useful in pregnancy, a condition associated with increased baseline D-dimer levels. Several tools have been developed to limit the need for imaging and therefore avoid radiation exposure to the mother and developing fetus. The "LEFt Rule" uses three variables (symptoms in the left leg [L], calf circumference difference ≥ 2 cm [E], and first-trimester presentation [Ft]), with excellent negative predictive value with none of the variables present and increasing risk with the number of variables present.[22,159] Additionally, the YEARS criteria (signs or symptoms of DVT, hemoptysis, PE as most likely diagnosis) paired with a higher D-dimer threshold have been used to limit the need for imaging to diagnose or exclude VTE in pregnancy[160] (Fig. 73-6). In pregnant women, the diagnosis of DVT by ultrasonography should be leveraged to establish the presence of PE without imaging the chest. In those with normal compression ultrasound, both (1) presence of no YEARS criteria and (2) one to three criteria with D-dimer <500 ng/mL effectively ruled out PE. Those with one to three YEARS criteria and D-dimer <500 ng/mL require imaging to exclude PE.

The optimal imaging to diagnose PE during pregnancy remains in flux.[161,162] Most would prefer $\dot{V}/\dot{Q}$ scanning if the woman has a normal chest x-ray. The radioactive albumin is excreted in the urine, and a Foley catheter should be placed to immediately drain the bladder and limit fetal radiation exposure. If the CXR is abnormal or $\dot{V}/\dot{Q}$ scanning is not immediately available, the recommendation should be to shield the gravid uterus with lead and obtain a CT pulmonary angiogram. This does still expose the fetus to internal scatter radiation but is most likely to yield a diagnostic result and not require further radiation exposure.

Due to the teratogenic potential of warfarin and the potential for DOACs to cross the placenta, as well as lack of safety data, UFH or LMWH should be used in pregnant women who develop VTE during pregnancy. Most would recommend LMWH earlier in pregnancy with consideration to switching to UFH closer to the due date due to short half-life. The ideal anti-Xa target for treatment in pregnancy has not been thoroughly investigated.[163] Since the risk of VTE may be highest in the postpartum period, anticoagulation should be continued for at least 3 to 6 months, including a minimum of 4 to 6 weeks after delivery.

Malignancy-associated VTE

Patients with cancer represent a high-risk population for both recurrent thrombosis and bleeding complications. The malignant tumors release tissue factor that, in turn, initiates the clotting cascade. The release of inflammatory cytokines in response to the malignancy, as well as the inflammatory response to chemotherapy, further promotes the hypercoagulable state.[164] Until recently, LMWH was the preferred anticoagulant due to fewer recurrent thromboembolic events and bleeding complications compared with warfarin in the CLOT trial.[165] Recent randomized clinical trial data now demonstrate similar reduction in VTE recurrence with apixaban and edoxaban compared with LMWH.[166,167] Pilot data exist supporting the safety of rivaroxaban as well.[168] The rates of bleeding in these were similar between apixaban and LMWH but slightly higher with edoxaban and rivaroxaban, driven by increased major bleeding in DOAC-treated patients with gastrointestinal malignancy.

Chronic Thromboembolism

Anatomic resolution of PE is rarely complete, and these persistent perfusion defects can lead to dyspnea by either development of pulmonary hypertension or significant dead space ventilation. In a few, the residual thromboembolic burden is sufficiently extensive to cause resting pulmonary hypertension, a condition termed *chronic thromboembolic pulmonary hypertension (CTEPH)*. Estimates of the incidence of CTEPH in patients actively surveyed after acute PE range from 0.5% to 8.8% following an initial episode of acute PE, to 13.4% following recurrent episodes.[169] Approximately 25% of patients who develop CTEPH have no documented history of acute DVT or PE, and this feature greatly impedes the diagnosis. Anticardiolipin antibodies or a lupus anticoagulant have been detected in approximately 10% to 20% of patients and elevated factor VIII levels detected in 40%.[170] No other defined thrombophilic or fibrinolytic abnormality has been encountered in this population. Age greater than 70, systolic pulmonary artery pressure (PASP) greater than 50 mm Hg at the time of diagnosis of acute embolism, systolic PASP greater than 50 mm Hg at the time of hospital discharge following acute PE, previous PE, prior splenectomy, ventriculo-atrial shunts, the presence of antiphospholipid antibodies, and a larger degree of pulmonary vascular obstruction at the time of acute PE have been identified as risk factors for CTEPH.[171]

The optimal management of CTEPH is surgery (pulmonary thromboendarterectomy or PTE), which involves the dissection of endothelialized thrombi under cardiopulmonary bypass and

Nonthrombotic pulmonary embolism. Eur Respir J. 2009;34(2):452–474.)*

deep hypothermia.[172] For the majority of patients, successful PTE is considered curative. However, the hemodynamic outcome is incomplete in approximately 20% of patients. When PTE is not an option due to the distal nature of the disease or the comorbidities convey a prohibitive risk, pulmonary arterial hypertension–targeted pharmacotherapy with riogicuat[173] and balloon pulmonary angioplasty represent potential therapeutic alternatives.[174] Regardless of management, therapeutic anticoagulation should be continued indefinitely in all patients with CTEPH.

OTHER VARIETIES OF EMBOLIC DISEASE

Although the majority of cases of PE are the result of thrombus migration (hence *thrombo* embolism), other materials may occasionally obstruct the pulmonary vascular bed (Fig. 73-16).[175] Because the lung receives all of the blood flow returned from the venous system, the pulmonary vascular bed serves as a "sieve" for all particulate substances entering the venous blood and is the first vascular bed to be exposed to any toxic substance injected intravenously. As a result of its strategic position, the pulmonary vascular bed is, therefore, exposed to a wide variety of potentially obstructing and injurious agents.

■ Venous Air Embolism

An increasingly common form of nonthrombotic embolism is venous air embolism. The increasing frequency of the problem reflects the wide variety of invasive surgical and medical procedures now available, the broad use of indwelling central venous catheters, the use of positive-pressure ventilation with high levels of positive end-expiratory pressure, and the frequency of thoracic and other forms of trauma.[176] The simple inadvertent transection or loss of closure of a large-bore intravenous catheter, particularly in the jugular or subclavian vein, can result in ingress of substantial quantities of air. Air bubbles enter the pulmonary vascular bed and, from there, can enter the arterial system and be diffusely distributed throughout the body by way of either an intracardiac shunt (atrial septal defect, patent foramen ovale) or, more likely, through microvascular pulmonary shunts.

Physiologic consequences are related to the volume of air entrainment and rate of accumulation. An abrupt rise in pulmonary artery pressure and noncardiogenic pulmonary edema may develop, lung compliance falls, and hypoxemia ensues. The symptoms of venous air embolism are variable and nonspecific, and they may include alterations in sensorium, chest pain, dyspnea, or a sense of impending doom.[177] These and other consequences appear to be due to two phenomena: actual lodgment of the bubbles in capillary beds that interfere with nutrient supply to the affected organs, and the formation of platelet–fibrin aggregates, creating diffuse microthrombi. Thrombocytopenia may be seen as a consequence of this latter event. The most serious consequences result from cerebral or coronary artery air embolism, with the severity of the consequences depending upon the rate and volume of air gaining access to the circulation.

The best approaches to air embolism are prevention and early detection. Treatment consists of measures designed to restore flow and promote reabsorption of the intravascular air.[178] Measures designed to restore flow include patient positioning (Trendelenburg position, with the left side down), removal of air through central venous catheters or direct needle aspiration, and closed chest cardiac massage. Measures designed to increase absorption include the use of 100% oxygen and hyperbaric oxygen therapy. Using such aggressive measures, mortality from venous air embolism has been dramatically reduced.

■ Fat Embolism

Another reasonably frequent and dramatic form of nonthrombotic embolism is fat embolism.[179] A rather characteristic syndrome follows entry of neutral fat into the vascular system, consisting of the onset of dyspnea, hypoxemia, petechiae, and mental confusion. Seizures and focal neurologic deficits have been described. There is a variable lag time of 24 to 72 h in the onset of the syndrome following the inciting event; rarely, cases occur within 12 h or as late as 2 weeks after the event.

By far, the most common inciting event is traumatic fracture of long bones, with incidence rising with the number of fractures and with fractures involving the femur.[180] However, orthopedic procedures and trauma to other fat-laden tissues (e.g., fatty liver) occasionally can be followed by the same syndrome. Although considerably less common, fat embolism syndrome has been reported following both liposuction and lipoinjection procedures.

The basis for the variability in the incidence and severity of the syndrome after apparently comparable injuries has not been well defined; neither has the reason for the delay in clinical presentation been explained. The pathophysiologic consequences appear to derive from two events: (1) actual vascular obstruction by neutral particles of fat; and (2) the injurious effects of free fatty acids released by the action of lipases on the neutral fat. The latter effect is probably the more important, causing diffuse vasculitis with leakage from cerebral, pulmonary, and other vascular beds. The time necessary to produce toxic intermediaries may explain the delay from the inciting event to clinical presentation.

The diagnosis of fat embolism syndrome is a clinical one, suggested by the onset of dyspnea, neurologic abnormalities, petechiae, and fever in the proper clinical context. Petechiae, typically distributed over the head, neck, anterior chest, and axillae, are present in only 20% to 50% of cases and are often evanescent. Therefore, their absence should not preclude consideration of the disease. No laboratory test is diagnostic of the syndrome. Fat can be demonstrated in the serum of a majority of patients with long bone fractures, so this finding is not specific for fat embolism syndrome. Similarly, the finding of lipid-laden macrophages in bronchoalveolar lavage fluid is common in patients with traumatic injuries irrespective of the presence of fat embolism syndrome.

Although a variety of treatments have been suggested (e.g., intravenous ethanol, albumin, dextran, heparin), none has proved effective. The role of corticosteroid therapy to prevent the onset of fat embolism syndrome after an inciting event remains controversial.[181] Supportive treatment, including mechanical ventilatory support when necessary, is the primary approach, and survival is now the rule with meticulous support.

Amniotic Fluid Embolism

Amniotic fluid embolism is a rare but unpredictable and catastrophic complication of pregnancy. It represents a leading cause of maternal mortality and is reported to occur in approximately 2.0 per 100,000 deliveries.[182] This disorder occurs during or after delivery when amniotic fluid gains access to uterine venous channels and, therefore, to the pulmonary and general circulations. The diagnosis is confirmed when four criteria are present (Table 73-13): (1) sudden-onset cardiopulmonary arrest or hypotension with respiratory compromise; (2) disseminated intravascular coagulation (DIC); (3) clinical onset during labor or within 30 min of placental delivery; (4) absence of fevers.[183] Exclusion of PE as an alternative diagnosis is important. Cesarean delivery, instrumented vaginal delivery (use of forceps), placental abnormalities (previa, abruption, accreta), and preeclampsia or eclampsia have been associated with increased risk of amniotic fluid embolism.[184]

TABLE 73-13 Diagnostic Criteria for Amniotic Fluid Embolism

- Sudden onset of cardiopulmonary arrest, **or** both
  Hypotension (systolic blood pressure <90 mm Hg) **and**
  Respiratory compromise (dyspnea, cyanosis, or hypoxia [SPO_2 <90%])
- DIC following initial symptoms[a]
- Onset during labor or within 30 minutes of delivery
- No fever (>38.0°C) during labor

All four criteria must be met to confirm diagnosis.

[a] A score of greater than 3 using the following three variables is compatible with disseminated intravascular coagulopathy:
Platelet count >100,000/mL = 0; Platelet count <100,000/mL = 2
PTT increase <25% = 0, 25–50% = 1, >50% = 2
Fibrinogen level >200 mg/L = 0; <200 mg/L = 1

Amniotic fluid contains particulate materials that can cause pulmonary vascular obstruction, but the major pathogenic mechanism of the syndrome remains uncertain. Amniotic fluid has thromboplastic activity that leads to extensive fibrin deposition in the lung vasculature and, occasionally, other organs. As a consequence of fibrin deposition, severe consumptive coagulopathy develops, including marked hypofibrinogenemia and thrombocytopenia. Following the acute event, an enhanced fibrinolytic state often occurs.

Although various forms of therapy have been suggested (e.g., antifibrinolytic agents such as aminocaproic acid, cryoprecipitate), the best approach is supportive. This supportive care includes vasopressors, intubation and mechanical ventilation, and consideration for ECMO. Despite these efforts, maternal mortality in amniotic fluid embolism remains high with the best estimates of mortality at 20%.[185]

Septic Embolism

Septic embolism is increasing in frequency owing to widespread IV drug abuse and the expanding use of indwelling intravenous devices.[186] Previously, septic embolism was almost exclusively a complication of septic pelvic thrombophlebitis due to either septic abortion or postpuerperal uterine infection.[187] However, almost any venous structure can be involved, either as a focus of primary infection or from intravascular or contiguous spread: septic cavernous sinus thrombosis resulting from meningitis, sinusitis, or facial cellulitis; septic portal venous thrombosis resulting from diverticulitis or liver abscess; or septic tonsillar or internal jugular venous thrombosis (Lemierre syndrome) resulting from oropharyngeal infection with *Fusobacterium* species. Increasingly common causes are those related to IV drug use and to infected intravascular catheters.[188]

Microscopically, septic phlebitis consists of purulent material admixed with fibrin thrombus. Embolization of this material can result in obstruction of small pulmonary vessels, but the major consequence is pulmonary infection. Characteristically, the chest x-ray or chest CT demonstrates scattered wedge-shaped pulmonary infiltrates that undergo cavitation. An increasing number of such infiltrates develops over periods of hours to a few days. Symptoms and signs include fever, dyspnea, cough, pleuritic chest pain, and hemoptysis. Initial treatment consists of appropriate antimicrobial drugs. If an indwelling catheter is the source of the infection, it should be removed. If there is not a prompt response to this regimen, surgical isolation of the septic vein, if present, should be considered. The role of systemic anticoagulation remains uncertain. Endocarditis may complicate septic phlebitis or mimic it.

Tumor Embolism

Involvement of the pulmonary vascular bed by tumor cells is not unusual given the frequency with which circulating tumor cells can be identified in patients with a wide range of malignancies and the frequency with which tumor emboli are discovered as an incidental finding at autopsy.[189] Tumor embolism becomes clinically apparent, however, in only a minority of patients with malignancy.

Microvascular tumor embolism is associated with a wide range of malignancies, the most common sites of origin being the mucin-producing adenocarcinomas of the breast, lung, prostate, stomach, and liver. Renal cell carcinoma may invade the renal vein with serpiginous spread into the inferior vena cava and has been associated with tumor emboli. Tumor embolism of large fragments occurs rarely and may mimic acute thromboembolic disease. In this setting, survival following tumor embolectomy has been reported.

The clinical presentation of microvascular tumor embolism is typically subacute and involves progressive dyspnea, tachycardia, and tachypnea. Jugular venous distention, a prominent P2, tricuspid regurgitation, or a right-sided S3 may be present on physical examination if the extent of pulmonary vascular obstruction is sufficient to cause pulmonary hypertension.

The development of pulmonary hypertension is a common accompaniment of symptomatic, microvascular tumor embolism and remains a major cause of mortality. Pulmonary hypertension appears to result from both an obliteration of the pulmonary vascular bed by an admixture of tumor cells and thrombus as well as the development of medial hypertrophy, intimal fibrosis, and fibrinoid necrosis encountered in other etiologies of pulmonary hypertension.

Hypoxemia and a compensated respiratory alkalosis are commonly present. The chest radiograph is most often normal, but focal or diffuse infiltrates, which may be fleeting, have been described. $\dot{V}/\dot{Q}$ scanning most commonly demonstrates a mottled appearance or peripheral, subsegmental defects; segmental or larger defects, indistinguishable from those associated with thromboembolic embolism, may occur in those rare instances of large-vessel involvement. CT may demonstrate peripheral, wedge-shaped defects consistent with infarcts; a pattern of multifocal dilatation and beading of the peripheral pulmonary arteries has been described.[177]

Pulmonary angiographic findings may include delayed vascular filling, pruning, and tortuosity, similar to that seen in other forms of small-vessel pulmonary hypertension. The angiographic findings in large-fragment tumor embolism may be indistinguishable from those seen in acute PE. The optimal diagnostic approach has not been agreed upon. Open lung biopsy, bronchoalveolar lavage, and aspiration of blood from a wedged pulmonary artery catheter may have roles in the approach, but aggressiveness of the diagnostic approach should be individualized and based on the prognosis of the underlying malignancy as well as the patient's preferences.

The differential diagnosis of tumor embolism includes thrombotic embolism, parenchymal metastasis, lymphangitic carcinomatosis, malignant pericardial effusion, and chemotherapy-related lung toxicity. The premortem diagnosis is often one of exclusion. Parenchymal metastasis, lymphangitic carcinomatosis, and chemotherapy-related lung toxicity can be differentiated from tumor embolism by findings on high-resolution CT. Differentiation of tumor embolism from thrombotic embolism may be somewhat more problematic, especially if there is large-vessel involvement.

■ Other Emboli

Because of its sieve function, the pulmonary vasculature may also be the target of a wide variety of other materials that enter the venous system.[190] Trophoblastic tissue can escape the uterus and lodge in the pulmonary circulation during pregnancy. After head trauma, brain tissue has been found in the lungs; the same is true of liver cells following abdominal trauma and bone marrow after cardiopulmonary resuscitation. Pulmonary cement embolism is a rare but known complication of vertebroplasty.[191]

Noninfectious vasculitic-thrombotic complications occur in association with the illicit intravenous use of crushed tablets intended for oral administration. Medications associated with pulmonary complications include methylphenidate hydrochloride, oral opiates (pentazocine, meperidine, methadone), and antihistamines. Particulate and irritant drug carriers (e.g., talc, cellulose) and occasionally the drugs themselves may cause vascular inflammation and secondary thrombosis. The clinical presentation is diverse and includes diffuse micronodular opacities, lower lobe emphysema, diffuse interstitial fibrosis, and progressive massive fibrosis.[192] Repetitive insults may lead to severe and irreversible pulmonary hypertension. In many IV drug users, perfusion scans demonstrate segmental or smaller defects. The diagnosis is often suggested by the clinical history. Radiographic findings include small, diffuse, well-defined nodular densities. These nodules may progress, and massive fibrosis may ensue. Lower lobe panlobular emphysematous changes mimicking α1-antitrypsin deficiency also may be present. Diagnostic confirmation often requires lung biopsy, either open or transbronchial; many times, confirmation is not necessary if the imaging is consistent with talcosis and the patient admits to injection of crushed pills. Fundoscopic examination, revealing birefringent material in retinal vessels, is a noninvasive means of establishing the diagnosis. The prognosis is poor, with progressive pulmonary disease being the rule.[193]

CHAPTER 74

Pulmonary Vasculitis

Rodrigo Cartin-Ceba
Ulrich Specks

INTRODUCTION

Pulmonary vasculitis is usually a manifestation of a systemic disorder leading to inflammation of vessels of different sizes by a variety of immunologic mechanisms. Vasculitis can be separated into primary and secondary vasculitis. The primary systemic vasculitides are a heterogeneous group of syndromes of unknown etiology, which share a clinical response to immunosuppressive therapy (Table 74-1). Their wide spectrum of frequently overlapping clinical manifestations is defined by the size and location of the affected vessels as well as the nature of the inflammatory infiltrate. Secondary vasculitis may pose significant management problems in the context of a well-defined underlying disorder, such as diffuse alveolar hemorrhage caused by systemic lupus erythematosus. Alternatively, secondary vasculitis may be an incidental histopathologic finding, for instance, in the context of an infection or necrotizing sarcoid granulomatosis.

TABLE 74-1 Chapel Hill Consensus Nomenclature of the Primary Systemic Vasculitides

Name	Respiratory Manifestations	Presence of ANCA
Large vessel vasculitis		
Giant-cell arteritis	Rare	No
Takayasu arteritis	Frequent	No
Medium-sized vessel vasculitis		
Polyarteritis nodosa	Rare	No
Kawasaki disease	No	No
Small vessel vasculitis		
ANCA-associated vasculitis		
Granulomatosis with polyangiitis (Wegener)	Frequent	>80%
Microscopic polyangiitis	Frequent	>80%
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) syndrome	Frequent	>50%
Immune complex small vessel vasculitis		
Anti-GBM disease	Frequent	No
IgA vasculitis	Rare	IgA-ANCA reported
Cryoglobulinemic vasculitis	Rare	No
Hypocomplementemic urticarial vasculitis	Frequent	No
Variable vessel vasculitis	Rare	No
Behçet disease		

CLASSIFICATION AND DEFINITIONS

Classification schemes and definitions of the various forms of vasculitis have evolved over the past decades. Historically, the classification of the vasculitides has been based on the size of the most prominently affected vessels. The primary purpose of classification and nomenclature is to standardize communication between clinicians and investigators and to facilitate more uniform treatment approaches. Ideally, the classification system reflects the current understanding of pathogenesis. The first international consensus conference on the nomenclature of systemic vasculitides held in 1992 in Chapel Hill aimed to reconcile definitions and classification schemes used by European and American investigators. The resulting nomenclature and definitions were based mainly on histopathologic criteria, particularly the size of the vessels involved, but allowed for radiographic and clinical surrogates to fulfill the definitions. These definitions, nomenclature, and classification found wide acceptance. The terminology was revised and updated at the second 2012 Chapel Hill international consensus conference so that it reflects novel insights into the pathogenesis of various vasculitides while avoiding the use of eponyms as much as possible.[1] In this chapter, the specific definition of each form of vasculitis is discussed in detail as part of the description of the clinical manifestations and differential diagnosis of each entity.

The 2012 Chapel Hill nomenclature is clinically very useful to pulmonologists as it reflects the clinical and histopathologic pulmonary features and facilitates the therapeutic approach to individual patients. The three small vessel vasculitides that present most often with respiratory symptoms are granulomatosis with polyangiitis (GPA; formerly Wegener granulomatosis), microscopic polyangiitis (MPA), and eosinophilic granulomatosis with polyangiitis (EGPA; formerly Churg-Strauss syndrome). Most patients with these syndromes have antineutrophil cytoplasmic autoantibodies (ANCA) detectable in the serum at the time of initial presentation.[2] Consequently, this group of small vessel vasculitides is referred to *in cumulo* as "ANCA-associated vasculitis."

In patients with vasculitis, two types of ANCA are of clinical significance. In more than 80% of patients with GPA (Fig. 74-1), ANCA occurs and is associated with a cytoplasmic immunofluorescence pattern (C-ANCA) on ethanol-fixed neutrophils that react with the neutrophil granule enzyme proteinase 3 (PR3-ANCA). In

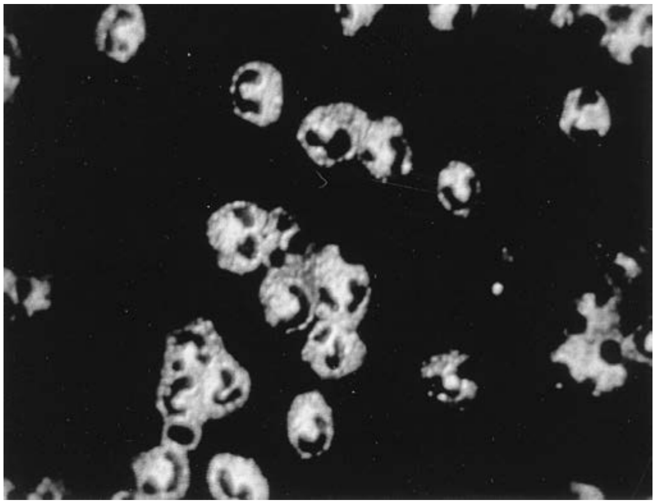

Figure 74-1 Cytoplasmic indirect immunofluorescence (C-ANCA) pattern in ethanol-fixed neutrophils caused by ANCA reacting with PR3.

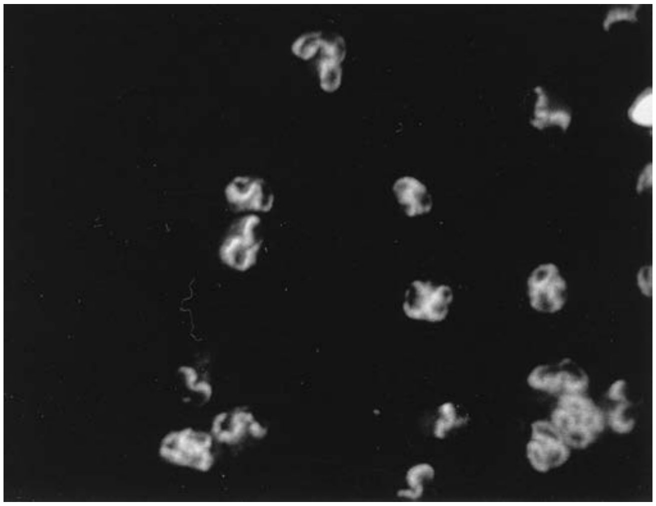

Figure 74-2 Perinuclear indirect immunofluorescence (P-ANCA) pattern in ethanol-fixed neutrophils caused by ANCA reacting with MPO.

contrast, ANCA that causes a perinuclear immunofluorescence pattern (P-ANCA) on ethanol-fixed neutrophils and reacts with myeloperoxidase (MPO-ANCA) occurs in fewer than 10% of patients with GPA but in the majority of patients with MPA (Fig. 74-2). MPO-ANCA are also the predominant type of ANCA encountered in patients with EGPA, in which PR3-ANCA is the exception. Despite these circulating autoantibodies, hardly any immunoglobulin deposits can be detected in the tissue lesions of ANCA-associated vasculitis, and they are consequently called “pauci-immune” lesions.

EPIDEMIOLOGY

The primary systemic vasculitides are rare, and few epidemiologic studies have been conducted, mostly in ethnically homogenous populations.[3] Giant-cell arteritis is the most frequent form of systemic vasculitis with an annual incidence of 13 per million adults (40 per million over the age of 60). It appears to be increasing in frequency and becoming cyclical over time. The latter observation has been interpreted as possibly suggesting a relationship with infections. Respiratory manifestations rarely represent significant management problems in these patients.

Various studies from different regions of the world report a fairly uniform annual incidence of one to two cases per million for Takayasu’s arteritis. Pulmonary vascular complications occur in about half of the afflicted patients. The estimated annual incidence of GPA has been rising over the decades from 0.5 to 0.7 per million during the 1970s and early 1980s to current estimates of about 10 to 12 per million. Similar increases in annual incidence have been observed for MPA and EGPA. The average frequency of MPA is similar to that of GPA; for EGPA it is estimated to be of the order of one to three per million. A recent population-based study of ANCA-associated vasculitis in Olmsted County, Minnesota from 1996 to 2015 identified an annual incidence of 3.3 per 100,000, with a prevalence of 42.1 per 100,000, which is substantially higher than the rates reported in other areas worldwide.[4] In this study, the incidence of GPA was similar to that of MPA.

The ANCA-associated vasculitides have different ethnic predilections: GPA affects predominantly whites, and northern Europeans appear more prone to develop GPA. In contrast, individuals of southern European and Mediterranean descent appear to be relatively more apt to develop MPA. GPA and MPA can affect individuals of any age. However, the incidence of GPA plateaus after age 50, whereas the likelihood of developing MPA continues to increase with age.

The annual incidence of the secondary vasculitides varies widely. The reported frequencies for rheumatoid vasculitis and vasculitis in systemic lupus erythematosus are 12.5 per million and 3.6 per million, respectively. Behçet disease has a peculiar geographic distribution along the old Silk Road, with the highest prevalence being reported from Turkey and central and far-eastern Asia, where the frequencies range from 100 to 380 per 100,000, compared with only 1 per 100,000 in western Europe.

The available population-based studies need to be interpreted with some caution because they do not distinguish between whether the observed increased incidence of systemic vasculitis is true or the result of more frequent recognition of the disease. Moreover, whether individual diagnoses are accurate and consistent is challenged by the changing definitions of the syndromes over time.

ANCA-ASSOCIATED VASCULITIS

Below we consider the ANCA-associated vasculitides, including granulomatosis with polyangiitis, microscopic polyangiitis, and eosinophilic granulomatosis with polyangiitis.

Granulomatosis with Polyangiitis: Clinical Presentation and Diagnosis

GPA is the most common form of vasculitis to involve the lung. The Chapel Hill Consensus Conference defined GPA as “necrotizing granulomatous inflammation usually involving the respiratory tract, and necrotizing vasculitis affecting predominantly small to medium-sized vessels.”[1] However, it is important to recognize that GPA is a systemic disease that can affect almost any organ (Table 74-2). The most frequently involved sites are the upper airways, lungs, and kidneys.[5] Symptoms and clinical disease manifestations are the result of necrotizing granulomatous inflammation and small vessel vasculitis that occur in variable degrees of combination.

In the 1960s the term *limited Wegener’s granulomatosis* was introduced to indicate patients with GPA who lacked renal disease. The use of this term and its implications have evolved over the last two decades. Even in the absence of renal involvement, patients may have life-threatening pulmonary or neurologic disease requiring aggressive immunosuppressive treatment. For instance, a patient who “only” has alveolar hemorrhage in the absence of glomerulonephritis should never be classified as having “limited” GPA. Consequently, today, the use of the term *limited GPA* implies that (1) the pathology is predominantly a necrotizing granulomatous inflammation, and the vasculitis seen on biopsy is of lesser clinical significance; and (2) there is no immediate threat either to the patient’s life or of irreversible damage to the affected organ. In this sense, “limited GPA” should now be avoided and replaced by *nonsevere GPA*, in contrast to “severe” GPA, which by definition either threatens the patient’s life (e.g., alveolar hemorrhage) or a vital organ with the risk of irreversible damage (e.g., rapidly progressive glomerulonephritis, scleritis, mononeuritis multiplex). These definitions and distinctions form the basis for stratification of current standard therapy defined in the 2021 American College of Rheumatology/Vasculitis Foundation Guideline for the Management of ANCA-associated vasculitis.[6]

More than 90% of patients with GPA first seek medical attention for symptoms arising from the upper and/or lower airway. Nasal and sinus disease is characterized by congestion and epistaxis due to mucosal friability, ulceration, and thickening. Patients may also have features of chronic sinusitis and recurrent or chronic serous otitis. Perforation of the nasal septum and/or saddle nose deformity may result from ischemia of the nasal cartilage (Fig. 74-3). Oral manifestations include gingival hyperplasia (Fig. 74-4) and oropharyngeal ulcerations. Subglottic stenosis occurs in approximately 20% of patients and can cause life-threatening compromise of the airway.

TABLE 74-2 Organ Systems Affected by ANCA-Associated Vasculitis

Feature	Granulomatosis with Polyangiitis (Wegener)	Microscopic Polyangiitis	Eosinophilic Granulomatosis with Polyangiitis (Churg-Strauss)
Upper airway disease	90%–95%	No	50%–60%
Pulmonary parenchymal disease	54%–85%	20%	30%
Alveolar hemorrhage	5%–15%	10%–50%	<3%
Glomerulonephritis	51%–80%	60%–90%	10%–25%
Gastrointestinal tract	<5%	30%	30%–50%
Eyes	35%–52%	<5%	<5%
Nervous system	20%–50%	60%–70%	70%–80%
Heart	8%–16%	10%–15%	10%–15%
Skin	33%–46%	62%	50%–60%
Eosinophilia	Rare	Rare	Yes
Asthma	No[a]	No[a]	Yes
Granulomatous inflammation	Yes	No	Yes

[a] *Not more than general population.*

Subglottic stenosis may occur in the absence of other features of active GPA. Symptoms include dyspnea, hoarseness, cough, or stridor; the latter is occasionally mistaken for wheezing.

GPA involving the lower airways can affect the pulmonary parenchyma, the bronchi, and rarely the pleura.[7–9] Presenting features of parenchymal involvement may include cough, dyspnea, chest pain, or hemoptysis. However, some patients may be completely asymptomatic. Patients with diffuse alveolar hemorrhage usually present with acute or progressive dyspnea and anemia (Fig. 74-5). Hemoptysis is absent in about one-third of patients. Patients with diffuse alveolar hemorrhage may deteriorate rapidly and experience respiratory failure, which has a mortality rate up to 50%.

The clinical presentation of diffuse alveolar hemorrhage is caused by pulmonary capillaritis (Fig. 74-6). The predominant inflammatory cells are neutrophils. However, eosinophils or monocytes also may be present. Capillaritis usually causes fibrinoid necrosis of alveolar and vessel walls and may culminate in the destruction of the underlying architecture of the lung. An important hallmark of capillaritis is the presence of pyknotic cells and nuclear fragments from neutrophils undergoing apoptosis, a feature called *leukocytoclasis*. This hallmark enables distinction between true capillaritis and margination of neutrophils related to surgical trauma. Depending on the

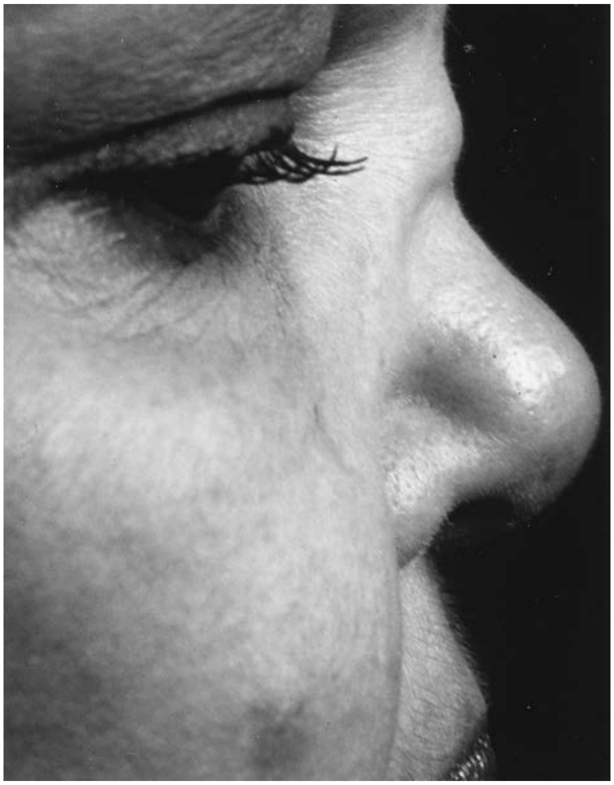

Figure 74-3 Saddle nose deformity of granulomatosis with polyangiitis.

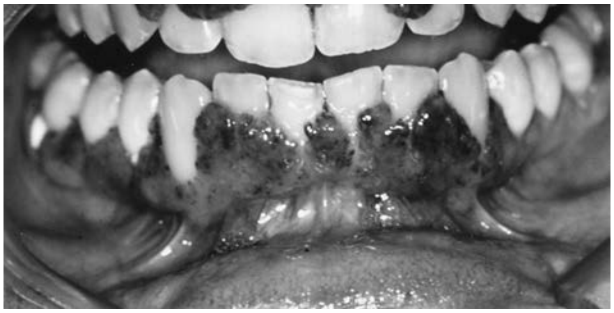

Figure 74-4 Strawberry or mulberry gums in a patient with granulomatosis with polyangiitis.

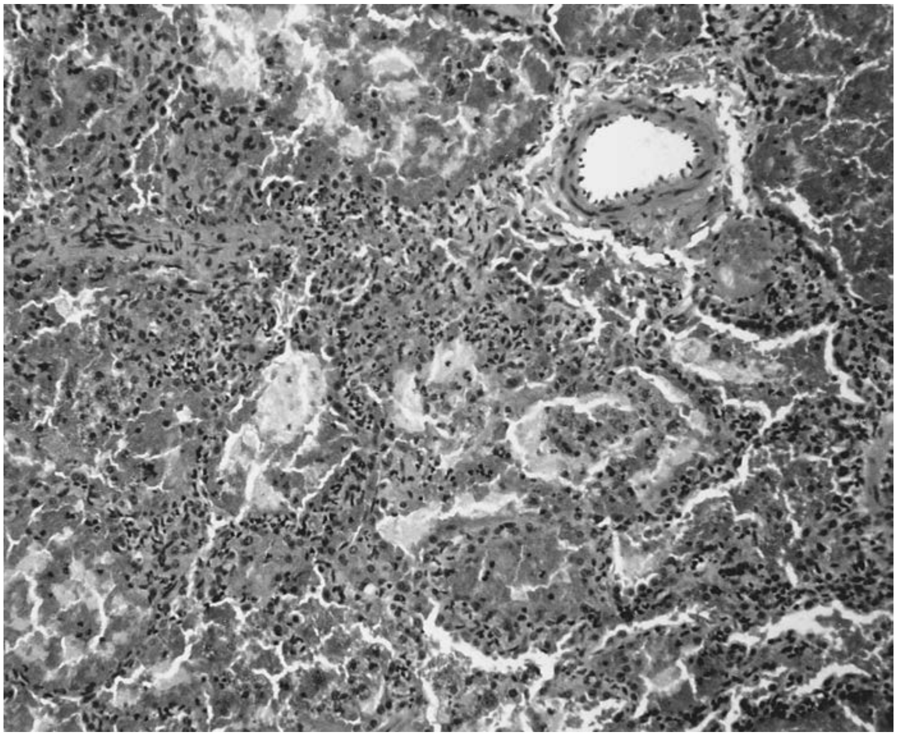

Figure 74-6 Alveolar capillaritis causing pulmonary hemorrhage in granulomatosis with polyangiitis.

acuteness and duration of alveolar hemorrhage, hemosiderin-laden macrophages and interstitial hemosiderin deposits may be present.[10]

The most common form of pulmonary involvement in GPA is caused by necrotizing granulomatous inflammation and presents radiographically as nodules or mass lesions, which may cavitate (Figs. 74-7, 74-8, and 74-9). These lesions may be incidental findings on thoracic imaging studies as they cause few symptoms and do not result in significant abnormalities of pulmonary function. Prominent air–fluid levels can be seen when the necrotic center of the inflammatory lesion becomes superinfected (Fig. 74-8). These necrotizing granulomatous lesions are a disease-defining feature of GPA.[1] Their presence easily separates GPA from MPA. In the absence of other features of small vessel vasculitis in other organs, infections, particularly with fungal organisms or *Nocardia*, organizing pneumonia, and malignancies are the main differential diagnostic considerations.[11,12] The differential diagnosis of GPA can be particularly challenging when the disease manifestations are limited to the lung and when patients are ANCA negative. Organizing pneumonia represents a noteworthy challenge because cryptogenic organizing pneumonia can be radiographically indistinguishable from GPA, organizing pneumonia can occur in GPA, and, like GPA, cryptogenic organizing pneumonia responds to glucocorticoids.[9] Multiple bilateral pulmonary nodules require histopathologic investigation to exclude metastatic disease or lymphoproliferative disorders. Lymphomatoid granulomatosis is a mimic of GPA, as this rare, angiocentric, angiodestructive, Epstein–Barr virus–related, T-cell rich B-cell lymphoma also often affects different extrapulmonary organs.[13]

To establish the histopathologic diagnosis based on pulmonary nodules or masses, video-assisted thoracoscopic surgical (VATS) lung biopsy has the highest diagnostic yield, but only patients with isolated lung involvement require this approach to establish a diagnosis. Bronchoscopy may be useful in patients with suspected GPA to obtain samples for cytology and microbiologic studies.

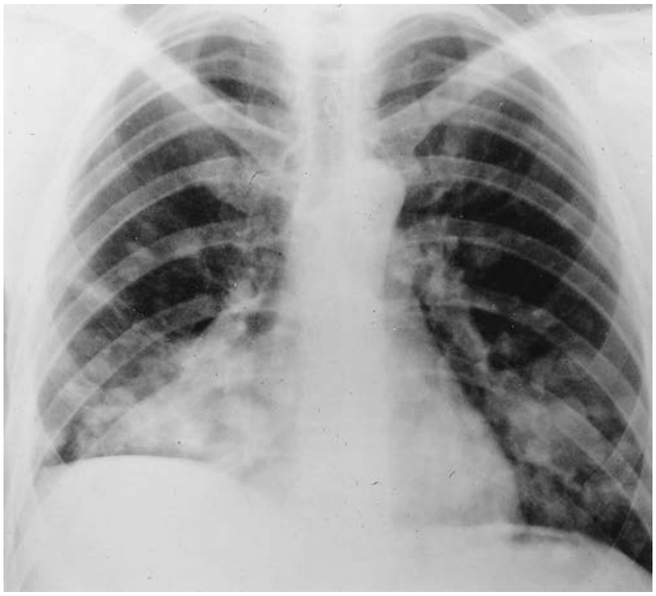

Figure 74-7 Chest radiograph of a patient with granulomatosis with polyangiitis displaying multiple nodules with and without cavitation.

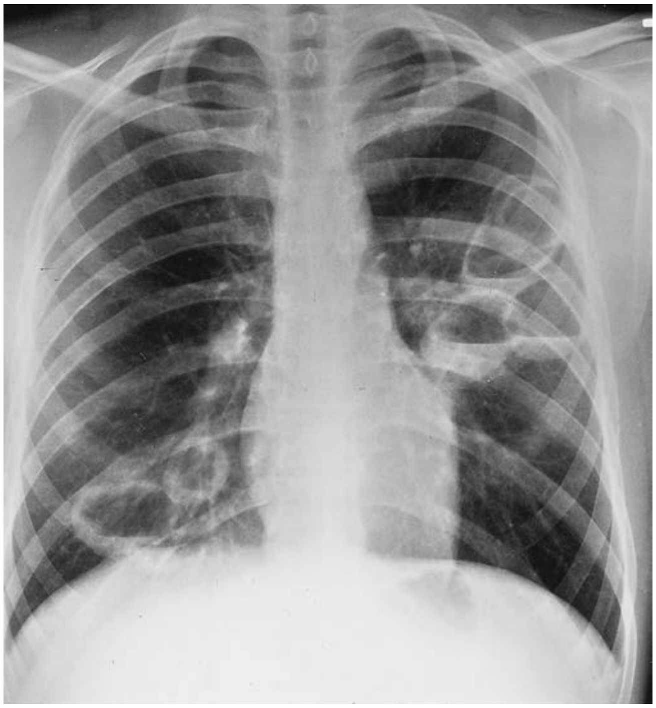

Figure 74-8 Chest radiograph of a patient with granulomatosis with polyangiitis showing multiple large cavities, some with air–fluid levels.

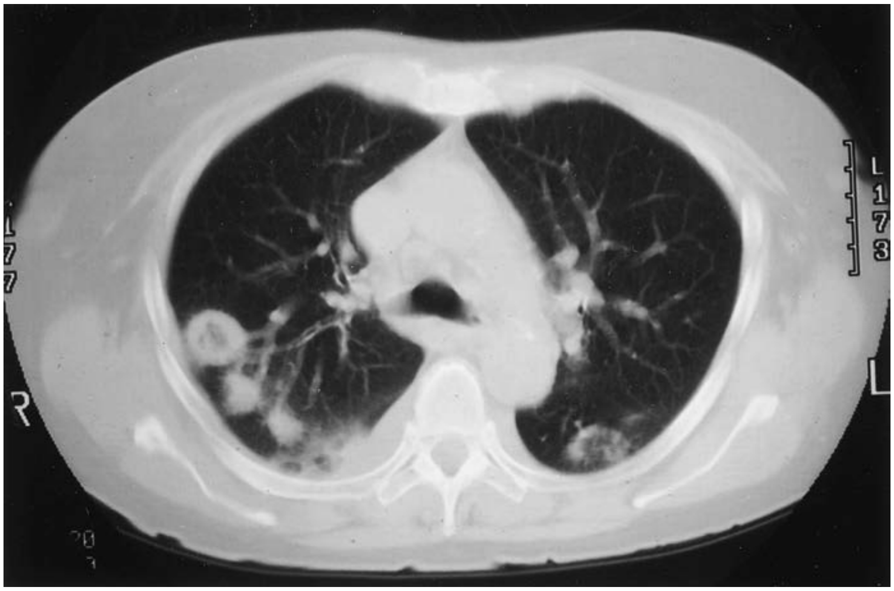

Figure 74-9 Computed tomography scan of a patient with granulomatosis with polyangiitis showing multiple nodules, some with cavitation. There are also small bilateral pleural effusions.

Transbronchial lung biopsy specimens support the diagnosis of GPA in about 50% of patients in conjunction with other supportive clinical features or positive ANCA test results but are diagnostic by themselves in only 20% of cases.[14] CT-guided core needle biopsy may be the preferred approach for peripheral lesions.

The lung nodules of GPA have very characteristic histopathologic features. Small necrotizing microabscesses appear to be the earliest lesion. They enlarge and coalesce until the typical geographic and basophilic appearance of the necrosis has developed (Fig. 74-10). The necrotic center is surrounded by palisading histiocytes and scattered giant cells. Occasionally the necrosis may be bronchocentric. When this type of necrotizing granulomatous inflammation extends into the walls of small vessels it is referred to as *granulomatous vasculitis* (Fig. 74-11). In contrast to capillaritis, this type of vasculitis seems to be a secondary phenomenon of the necrotizing granulomatous inflammation affecting the lung parenchyma. The inflammatory background of the granulomatous necrosis and vasculitis consists of a mixed cellular infiltrate containing lymphocytes, plasma cells, scattered giant cells, and eosinophils. It may cause extensive parenchymal consolidation mimicking organizing pneumonia. Well-defined sarcoid-like nonnecrotizing granulomas are not found in GPA.

Tracheobronchial involvement is common in GPA, occurring in 15% to 55% of patients, but rare in MPA, and women are more frequently affected.[8,14,15] PR3-ANCA are more common than MPO-ANCA in patients with tracheobronchial inflammation, including subglottic inflammation and subsequent stenosis.[8,15] Tracheobronchial inflammation is viewed as a surrogate of necrotizing granulomatous inflammation, even though classic histopathologic features of GPA are rarely found in endobronchial biopsies. Endobronchial disease may be an incidental finding on bronchoscopy or present with cough, hemoptysis, wheezing, dyspnea, or symptoms related to atelectasis or postobstructive pneumonia. Biopsies of tracheobronchial lesions often show nonspecific mucosal inflammation, ulcerations, and stenosing fibrosis, but rarely vasculitis. The tracheobronchial inflammation of GPA is localized or patchy in distribution throughout the airway. Affected areas and normal-appearing airways are next to each other, a feature differentiating the tracheobronchial inflammation of GPA from that of relapsing polychondritis, which is much more diffuse.[16] Any level of the airway can be affected. Transmural inflammation is detectable by CT imaging of the chest, which can reveal significant thickening of the airway walls. Tracheo- or bronchomalacia may result from inflammation affecting tracheobronchial cartilages, and significant expiratory dynamic airway collapse may ensue, which is detectable by bronchoscopy or by dynamic expiratory chest CT.[17] The differential diagnosis of tracheobronchial involvement of GPA includes relapsing polychondritis,[16] inflammatory bowel disease,[18,19] sarcoidosis,[20] and infections, particularly with fungal organisms.[21] The differential diagnosis may be challenging because a minority of patients with GPA remain ANCA negative, whereas nonspecific ANCA or P-ANCA with or without MPO-ANCA specificity can occur in patients with relapsing polychondritis, inflammatory bowel disease, or infections.[22]

Spirometry including inspiratory and expiratory flow-volume loops may show characteristic abnormalities indicative of degree and location of airway narrowing. Subglottic stenosis represents a fixed airway obstruction resulting in flattening of both the inspiratory and expiratory loops. If the intrathoracic trachea, or more commonly, one or both mainstem bronchi are affected, flattening of the expiratory curve can be found.

Pleural effusions are an uncommon manifestation of GPA and are usually small, asymptomatic, and incidental findings (Fig. 74-9). Other thoracic manifestations of GPA include inflammatory pleural pseudotumors and hilar adenopathy. The latter should raise the suspicion of infection, sarcoidosis, or lymphoma.

Glomerulonephritis is among the most concerning disease manifestations of GPA

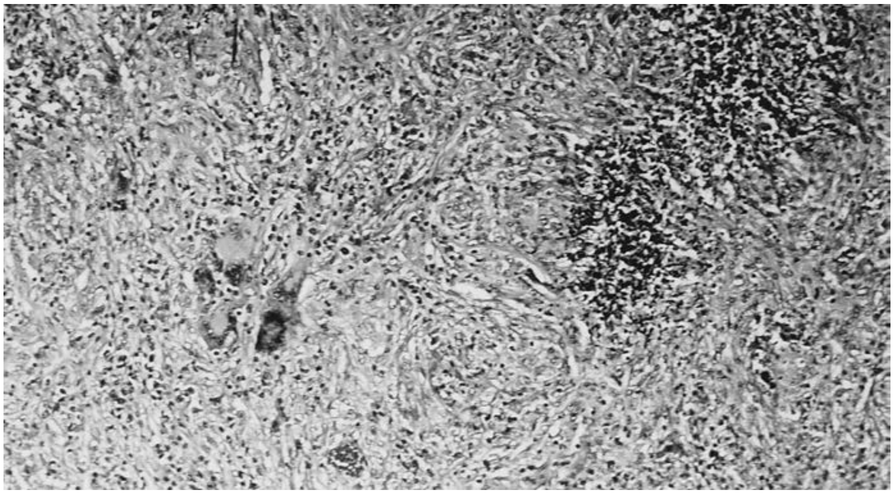

Figure 74-10 Geographic basophilic necrosis with palisading histiocytes and giant cells from a lung nodule in a patient with granulomatosis with polyangiitis.

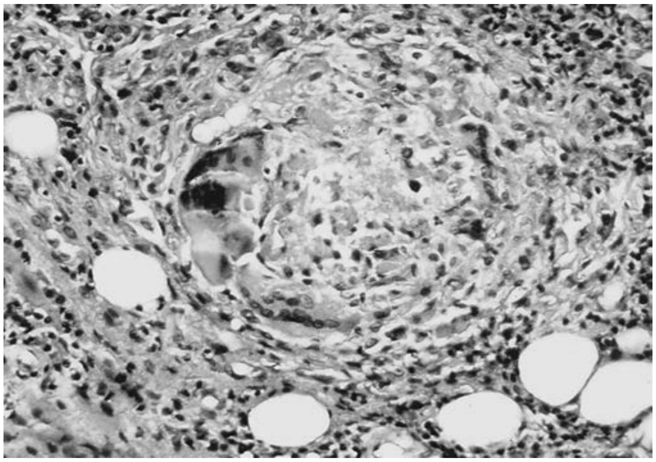

Figure 74-11 Granulomatous vasculitis with giant cells in a lung biopsy of a patient with granulomatosis with polyangiitis.

as it can progress to frank renal failure in the absence of symptoms. It is usually detected by the presence of abnormal laboratory results such as active urine sediment with microscopic hematuria and red cell casts, proteinuria, and declining renal function. Continued vigilance for glomerulonephritis is essential as it is present at diagnosis in less than half of all patients. However, over the course of their disease, the kidneys are affected in 80% of patients.

A renal biopsy is useful to establish a diagnosis of ANCA-associated vasculitis and to estimate the renal prognosis. The glomeruli are not affected uniformly (focal) by segmental, necrotizing inflammation (Fig. 74-12), and cellular crescents (Fig. 74-13) are frequently found. The number of glomeruli affected, degree of crescent formation, and destruction of individual glomeruli as well as the amount of sclerosis found determine the chance of recovery of renal function. In addition, tubular fibrosis and atrophy affect renal outcomes.[23] Direct immunofluorescence reveals no or only scant immune deposits (pauci-immune glomerulonephritis). Granulomatous inflammation affecting the renal parenchyma and tubulointerstitial nephritis rarely can be present.

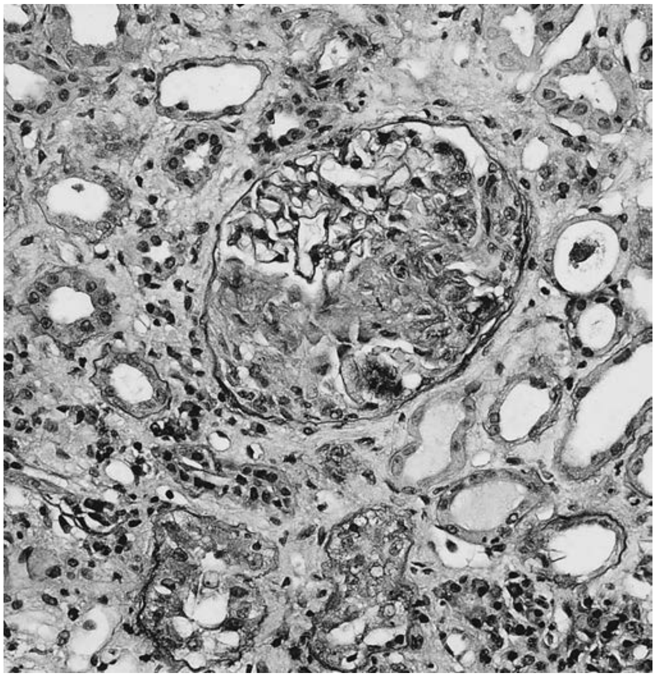

Figure 74-12 Focal necrotizing glomerulitis of granulomatosis with polyangiitis.

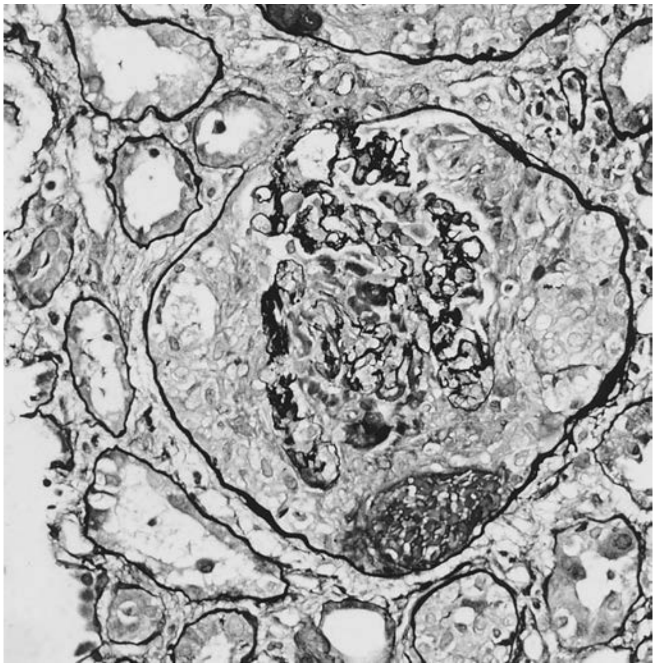

Figure 74-13 Rapidly progressive crescentic glomerulonephritis in granulomatosis with polyangiitis.

A wide spectrum of ocular manifestations has been observed in GPA, which may threaten vision by affecting the eye directly or involving its contiguous structures. Manifestations may include conjunctivitis, episcleritis, scleritis, keratitis, corneal ulceration, uveitis, and retinal vasculitis. Involvement of the lacrimal system may result in epiphora, dacryocystitis, and fistula. Retro-orbital inflammatory pseudotumors may affect one or both eyes, threaten the vision, and represent one of the most difficult challenges in the management of GPA (Figs. 74-14 and 74-15). Any patient with GPA who presents with eye pain or redness, proptosis, change in visual acuity, diplopia, or loss of visual field should be referred for emergent ophthalmologic consultation.

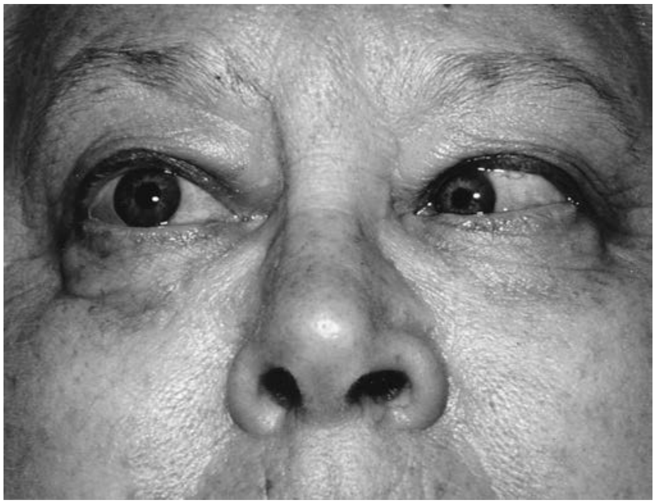

Figure 74-14 External ophthalmoplegia of the left eye due to orbital involvement with granulomatosis with polyangiitis.

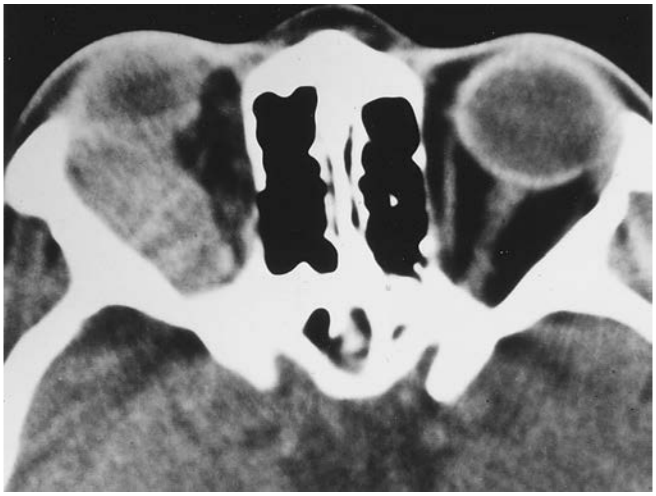

Figure 74-15 Computed tomography scan of the orbits in a patient with granulomatosis with polyangiitis showing a mass in the right orbit causing external ophthalmoplegia.

Nervous system involvement may occur in up to one-third of patients. Mononeuritis multiplex of the peripheral nervous system is caused by inflammation of the vasa nervorum. Central nervous system vasculitis and pachymeningitis represent severe disease manifestations with substantial risk of irreversible damage, persisting even after the acute inflammation is adequately controlled.

Cardiac involvement may be occult. Regional wall motion abnormalities with a noncoronary distribution pattern are frequent echocardiographic findings.[24] It is unclear whether this type of cardiomyopathy is the result of small vessel disease or inflammatory infiltration of the cardiac muscle. Pericarditis, valvulitis, and inflammatory pseudotumor also have been described.

A wide spectrum of cutaneous manifestations may be observed in GPA. Leukocytoclastic vasculitis presenting as palpable purpura is most common, followed by pyoderma gangrenosum-like lesions (Fig. 74-16) and so-called Churg-Strauss granulomas.

■ Microscopic Polyangiitis: Clinical Presentation and Diagnosis

Histopathologically, the necrotizing small vessel vasculitis of MPA causing necrotizing crescentic glomerulonephritis and pulmonary capillaritis is indistinguishable from that encountered in GPA.[25] Consequently, there is substantial overlap in organ manifestations and symptoms between the two syndromes (Table 74-2). A timely diagnosis of MPA may be delayed by a gradual onset or the nonspecific nature of symptoms such as fever, malaise, and weight loss. All organ systems may be involved. The kidneys are most commonly affected, involving up to 80% of patients. Another commonly encountered disease manifestation is diffuse alveolar hemorrhage due to pulmonary capillaritis, affecting 10% to 30% of patients. MPA is the most frequent cause of pulmonary-renal syndrome. Several cases of MPA in association with severe obstructive airways disease or bronchiectasis also have been described. More recently, several case series have highlighted an association between interstitial lung disease (ILD) and ANCA with or without MPA (see "Interstitial Lung Disease and ANCA with or without MPA," below).

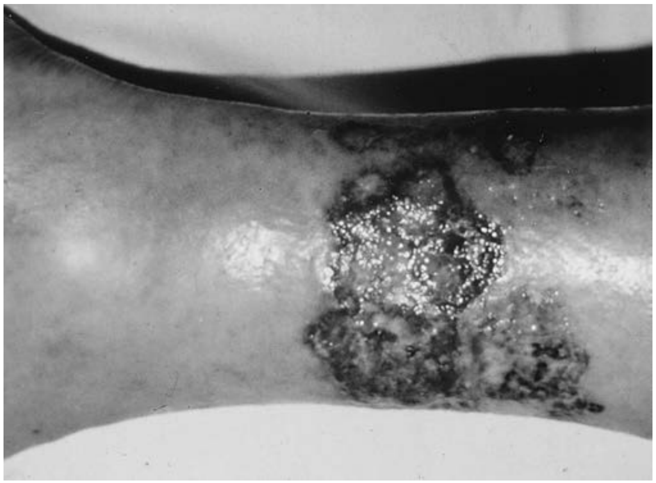

Figure 74-16 Pyoderma gangrenosum of the leg in a patient with granulomatosis with polyangiitis.

Palpable purpura caused by leukocytoclastic vasculitis of the skin, and musculoskeletal complaints, such as arthralgias and myalgias, also are common. Gastrointestinal involvement occurs in about one-third of patients. This is in contrast to GPA, in which gastrointestinal involvement is very rare. Visceral angiography is generally not helpful for the evaluation of abdominal symptoms, as the vessels involved are too small to be visualized. CT with or without contrast injection may be more helpful if gastrointestinal involvement is suspected. However, the use of contrast is relatively contraindicated in patients with active renal involvement. Sinusitis and asthma are rarely found in MPA, and their presence should lead to the consideration of an alternative diagnosis, particularly EGPA.

Most patients with MPA have ANCA, and in 40% to 80% they are of the P-ANCA variety, reacting with MPO. C-ANCA reacting with PR3 are seen less frequently. Occasionally patients with MPA later develop granulomatous inflammation and are reclassified as having GPA; this is more likely to occur in patients with C-ANCA.

As in GPA, a histopathologic diagnosis may be necessary to confirm the diagnosis before the patient is committed to prolonged immunosuppressive therapy. The biopsy specimen should be sought from the most accessible site. Renal biopsy shows pauci-immune focal segmental necrotizing glomerulonephritis, with extracapillary proliferation forming crescents. In contrast to GPA, granulomatous inflammation is not a feature of MPA. All other histopathologic features are indistinguishable from those of GPA. Treatment of MPA should follow the principles applied to the management of GPA[6]. Consequently, most cases of MPA require immunosuppressive therapy used for patients with severe GPA.

Interstitial Lung Disease and ANCA with or without MPA

A growing number of reports from all over the world have described patients with ILD who are ANCA positive, with or without signs or symptoms of MPA, as well as patients with MPA who also had ILD at the time of diagnosis.[26–30] Whether there is a pathogenic relationship between MPO-ANCA and pulmonary fibrosis, or whether lung fibrosis is a disease manifestation of ANCA-associated vasculitis rather than an independent comorbidity, remains unclear and controversial. A recent report from Japan identified an association of the MUC5B promotor polymorphism in patients with MPA who also had ILD, compared to patients with MPA without ILD and healthy controls, but similar to patients with ILD without MPA or patients with rheumatoid arthritis and ILD.[31] The ILD identified in the context of MPA usually has radiographic and histopathologic features of usual interstitial pneumonia (UIP) or of nonspecific interstitial pneumonitis (NSIP).[26,32] Atypical features including follicular bronchiolitis have also been reported.[26,33] Patients with ILD without signs of MPA may have ANCA. MPO-ANCA are the predominant ANCA type encountered, whereas PR3-ANCA occurs rarely. These patients may or may not have abnormal markers of inflammation, and signs or symptoms of MPA in other organs should be looked for. If ground-glass infiltrates are part of the ILD of a patient with MPO-ANCA, bronchoscopy with BAL is mandatory to rule out alveolar hemorrhage. Patients with ILD who are MPO-ANCA positive have a 25% chance of subsequently developing clinical features of MPA, a progression that has been documented for patients with MPO-ANCA, but not PR3-ANCA.[28,29]

In patients with MPA the presence of ILD is associated with increased mortality and determines their overall prognosis.[34] The vasculitis disease manifestations of these patients with MPA and ILD, including DAH superimposed on their ILD, respond to immunosuppressive therapy as expected for MPA, whereas the ILD may only respond if it has features of cellular NSIP or other inflammatory features. In contrast, if the lung fibrosis pattern is consistent with UIP, the lung fibrosis will not respond to immunosuppression given for the vasculitis features of the MPA. Consequently, once remission of the vasculitis has been induced with immunosuppression, patients with MPA and UIP should be offered treatment with antifibrotic agents.

■ Eosinophilic Granulomatosis with Polyangiitis: Clinical Presentation and Diagnosis

EGPA was originally described in 1951 as "allergic granulomatosis, allergic angiitis and periarteritis nodosa" by Jacob Churg and Lotte Strauss in a report based mostly on autopsy findings. The authors recognized the allergic background, blood and tissue eosinophilia with granulomatous inflammation leading to necrosis, and vasculitis; this combination reflects the final outcome of the disease before any mitigating therapy was available.[35] The syndrome subsequently known by its eponym, Churg-Strauss syndrome, for half a century was renamed at the 2012 Chapel Hill Consensus Conference on nomenclature of the vasculitides, and the new term intends to reflect the most prevalent pathology, pathogenic role of eosinophils, and similarities of the vasculitis shared with GPA and MPA.[1] It is because of the similarities of the small vessel vasculitis that EGPA is included among the ANCA-associated vasculitides even though only 40% to 70% of patients with active EGPA are ANCA positive.[36–38]

EGPA is the third type of vasculitis that commonly affects the lung. EGPA is primarily distinguished from GPA and MPA by a high prevalence of asthma and peripheral blood and tissue eosinophilia. Three distinct disease phases of the disease have been described. The first is a prodromal allergic phase with asthma. This phase may last for a number of years. The second is an eosinophilic phase with prominent peripheral and tissue eosinophilia. This phase may also last a number of years, and the manifestations may remit and recur over this time period. The differential diagnosis for patients in this phase of the disease includes parasitic infection, chronic eosinophilic pneumonia, and hypereosinophilic syndrome. The third vasculitic phase consists of systemic vasculitis and may be life threatening. The three phases are not seen in all patients and do not necessarily occur in this order; they may even coincide. However, asthma usually predates vasculitic symptoms by a mean of 7 years (range, 0–61). Formes frustes of EGPA have also been described with eosinophilic vasculitis and/or eosinophilic granulomas in isolated organs without evidence of systemic disease.

Pulmonary parenchymal involvement occurs in 38% of patients. Transient alveolar-type infiltrates are most common (Fig. 74-17). These have a predominantly peripheral distribution and are indistinguishable from infiltrates seen in chronic eosinophilic pneumonia. Occasionally, nodular lesions may be seen in EGPA. In contrast to GPA and MPA, alveolar hemorrhage is exceedingly rare. Renal involvement in EGPA is less prominent than in GPA and MPA and does not generally lead to renal failure. In contrast, peripheral nerve involvement, typically in the form of mononeuritis multiplex, is more frequent. The peripheral nerve involvement can result from both capillaritis and direct toxicity from eosinophil granule proteins. Skin, heart, central nervous system, and abdominal viscera also may be involved.

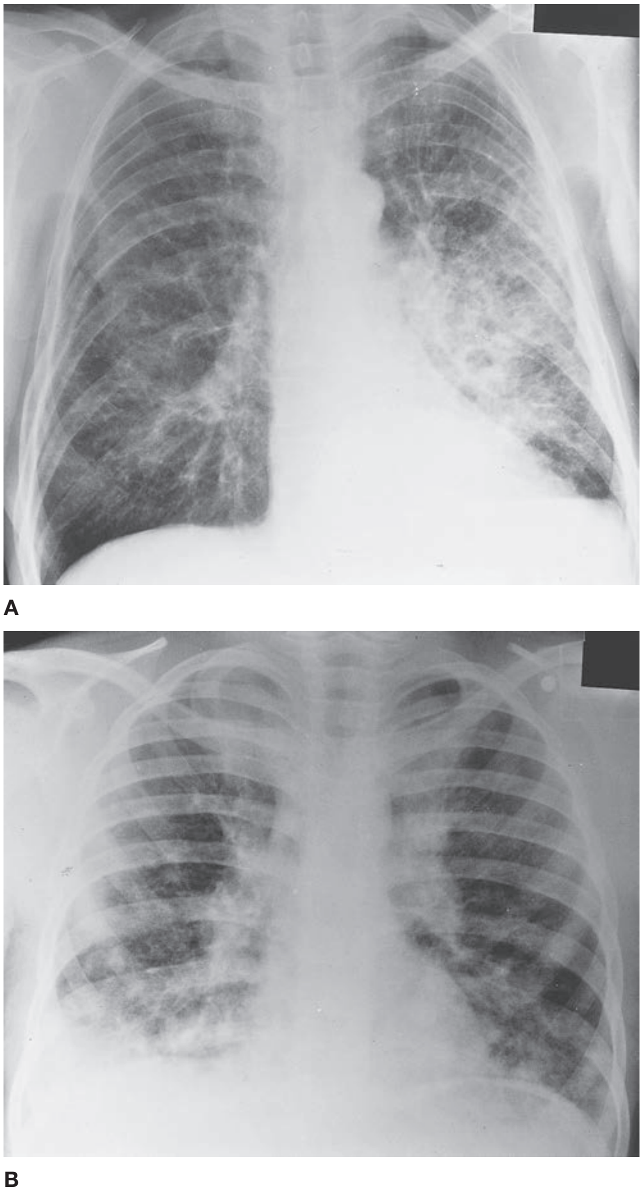

Figure 74-17 Chest radiographs of patients with eosinophilic granulomatosis with polyangiitis. **A.** Nonspecific gnomonic infiltrates. **B.** Multiple vague, patchy infiltrates. *(Reproduced with permission from Chumbley LC, Harrison EG, DeRemee RA: Allergic Granulomatosis and angiitis (Churg-Strauss syndrome): Report and analysis of 30 cases. Mayo Clin Proc. 1977;52(8):477–484.)*

The classic histopathologic picture consists of necrotizing vasculitis, eosinophilic tissue infiltration, and extravascular granulomas. However, not all features are found in every case, and they are not pathognomonic of the condition. Particularly the finding of a "Churg-Strauss granuloma" on skin biopsy should not be confused with the diagnosis of EGPA. While this type of necrotizing extravascular granuloma may be seen in EGPA, it may occur in other systemic autoimmune diseases, including GPA and rheumatoid arthritis.

If ANCA are present, they are usually P-ANCA reacting with MPO. The ANCA status appears to correlate with disease activity. Recent studies suggest a more vasculitic disease phenotype in the presence of ANCA, with ANCA being particularly frequent among patients with glomerulonephritis. Patients with heart involvement are less likely to be ANCA positive. However, not all studies have found this consistently, and there remains substantial overlap of organ manifestations between patients with EGPA who are ANCA positive and those who are ANCA negative.

Significant attention has been devoted to EGPA detected in patients using leukotriene receptor antagonists when these agents were first introduced into the management of asthma. Available case studies and limited population-based incidence estimates suggest that these agents may lead to unmasking of vasculitic symptoms in asthmatics, by allowing dose reductions or discontinuation of oral glucocorticoid therapy. There is no evidence suggesting that these agents cause EGPA.

The prognosis of EGPA is better than that of GPA and MPA. Most deaths are secondary to cardiac involvement, and patients should be carefully screened for signs and symptoms of cardiomyopathy, valvulitis, or pericarditis.[39]

Pathophysiology of ANCA-Associated Vasculitis

The etiology of ANCA-associated vasculitis remains unknown. Several different pathways and mechanisms have been proposed for the pathogenesis.[40,41] A genetic predisposition for autoimmunity, epigenetic factors, and environmental triggers seem to play a role in the development of ANCA-associated vasculitis. Currently available clinical and experimental evidence suggest that infections or other environmental exposures can lead to the loss of tolerance and an inflammatory environment that is conducive to the production of autoantibodies (ANCA) in predisposed patients. In the context of an inflammatory milieu, ANCA can cause specific tissue inflammation and injury by a variety of different mechanisms that involve direct interactions with PR3 or MPO.

Multiple studies have reported skewing in polymorphisms of a variety of immune response genes and genes encoding for ANCA target antigens and α_1-proteinase inhibitor with potential effects on disease outcome. A genome-wide association study found major histocompatibility complex (MHC) and non-MHC associations with GPA and MPA.[42] Notably, these syndromes were genetically distinct, but the strongest genetic associations were based on the antigenic specificity of the ANCA (PR3-ANCA vs. MPO-ANCA) rather than with the clinical syndrome (GPA vs. MPA). For PR3-ANCA-positive patients, strong associations were found with *HLA-DP*; the serpin A1 gene (*SERPINA1*), which codes for α1-antitrypsin, the major inhibitor of PR3; and the *PRTN3* gene, which encodes PR3. In patients with MPO-ANCA only an association with *HLA-DQ* was found.

The expression of ANCA-target antigens on the neutrophil surface, particularly PR3, is increased in patients with GPA and genetically determined. Moreover, epigenetic modifications that interfere with the normal silencing of genes coding for the ANCA-autoantigens in mature neutrophils may also contribute to the observed inappropriately increased expression of PR3 and MPO by these cells in patients with GPA or MPA.

Recent studies indicate that a separation of patients with ANCA-associated vasculitis by ANCA specificity (PR3-ANCA versus MPO-ANCA) provides a clinically more informative classification than the grouping by conventional phenotypic diagnosis (GPA versus MPA).[43] This concept is supported by results from genome-wide association studies discussed above,[42] analysis of cytokine patterns,[44] treatment response to rituximab,[45] and relapse risk.[46] Patients with limited GPA who remain ANCA negative rarely develop systemic vasculitic disease manifestations. Patients with glomerulonephritis and PR3-ANCA lose renal function much more rapidly than patients with MPO-ANCA. Patients with PR3-ANCA also have a higher relapse rate than patients with MPO-ANCA. Experimental data and animal models support a pathogenic role of ANCA in the development of vasculitis. Recent studies have also suggested a different clinical phenotype of ANCA-positive patients with EGPA compared with ANCA-negative patients.[47,48]

In GPA, the presence of PR3-ANCA appears most closely related to the development of vasculitic complications compared to patients who are ANCA-negative. Furthermore, systemic vasculitic relapses without recurrence of ANCA are extremely rare. Yet, remission may be maintained for extended periods of time in up to one-half of the patients despite the presence of ANCA. These clinical observations suggest that ANCA alone are not sufficient to cause disease activity, but ANCA seem to be required for the development of vasculitic complications of GPA and systemic relapses.

Many in vitro studies have demonstrated proinflammatory effects of PR3-ANCA and MPO-ANCA on neutrophils, monocytes, and endothelial cells, which enhance and perpetuate endothelial cell and tissue damage. ANCA may increase the adhesion of neutrophils to endothelial cells by enhancing the expression of cell adhesion molecules on endothelial cells. ANCA can activate primed neutrophils, resulting in the release of oxygen radicals and proteolytic enzymes. The latter may in turn induce endothelial cell apoptosis. ANCA-mediated neutrophil activation involves both Fc-γ-receptor engagement and recognition of expressed target antigen on the surface of primed neutrophils. ANCA may also cause endothelial cell damage by direct cytotoxicity or localized immune complex formation with target antigens bound to the endothelial cell surface. The latter may initiate localized complement activation. Finally, ANCA are thought to contribute to the recruitment of more inflammatory cells to the area of tissue injury by stimulating the release of chemotactic chemokines and agents from neutrophils, monocytes, and endothelial cells.

Rodent models of MPO-ANCA-associated vasculitis support the hypothesis of a pathogenic role of ANCA. They clearly indicate that ANCA contribute directly to the development of vasculitis and glomerulonephritis, and that the interaction of ANCA with its target antigen is required for the development of lesions. Furthermore, the localization of lesions is determined by the site of this interaction. At the same time, animal models support the significance of genetic determinants for the development of autoimmunity, vasculitis, and a specific phenotype with characteristic organ involvement and histopathologic features. Finally, animal model studies indicate that infections may be significant disease modifiers. Even though proinflammatory effects of murine PR3-ANCA could also be documented in vivo, the animals did not develop organ pathology typical of GPA or microscopic polyangiitis, and good animal models for PR3-ANCA-associated vasculitis remain elusive. This may be due to substantial differences between human and murine PR3, as the latter behaves more like human elastase than human PR3.

Many patients with ANCA-associated vasculitis relate the onset or recurrence of their disease to preceding infectious episodes, leading some to postulate the following mechanistic link. Most ANCA-mediated effects on neutrophils and monocytes require priming of the cells. This cytokine-dependent process is not unique to vasculitis. Cytokine stimulation of neutrophils and monocytes, typically by tumor necrosis factor (TNF), with resulting increased surface expression of ANCA target antigens, occurs normally in the context of infections. Patients with active vasculitis have indeed been shown to have both increased expression of ANCA target antigens on the surface of their neutrophils and elevated levels of TNF. In combination, these observations allow the hypothesis that neutrophil priming, which occurs in response to cytokine stimulation during infection, enables ANCA to interact with their target antigen on the neutrophil surface. This in turn sets the documented proinflammatory effects of ANCA in motion, aggravating and perpetuating the inflammatory reaction at the endothelial cell interphase.

To date, the causes of the production and persistence of ANCA remain poorly understood. Yet infections may be instrumental for the development of this specific type of autoimmunity. ANCA directed against a broad variety of target antigens have been documented in association with viral, fungal, bacterial, and protozoal infections. In the rare instances of C-ANCA/PR3-ANCA observed in infections, the ANCA disappeared with appropriate antimicrobial therapy. These observations suggest that ANCA can occur transiently in the setting of infection, and that the persistent ANCA response in patients with vasculitis may be the result of molecular mimicry in susceptible hosts. Subsequent diversification of T- and B-cell responses ("epitope spreading") may lead to responses against different epitopes on the same target molecule (intramolecular spreading) or extend to other molecules (intermolecular spreading). Bacterial superantigens also have been implicated in the pathogenesis of ANCA-associated vasculitis. GPA patients colonized with superantigen-producing *Staphylococcus aureus* are at high risk for relapse. GPA patients had expansion of T cell clones expressing Vβ genes specific for *S. aureus* superantigens more frequently than controls. This supports the theory that *S. aureus* contributes to the pathogenesis of vasculitis. By inducing potent T- and B-cell activity, superantigens produced during an *S. aureus* infection could initiate and maintain both ANCA production and cytokine release, thought to be required for the cascade that results in necrotizing granulomatous inflammation and vasculitis.

The crucial role of the alternative complement pathway for the development of capillaritis was first recognized in the murine model of MPO-ANCA-associated vasculitis. Specifically, the generation of activated complement factor 5 (C5a), which is a potent attractant and activator of neutrophils, via activation of the alternative complement pathway was shown to be necessary for the development of vasculitis.[41,49] Stimulation of neutrophils with C5a and ANCA not only results in the neutrophil respiratory burst and degranulation, but also activates the coagulation system and generates thrombin, thus bridging the inflammation and coagulation systems. In view of these results, targeting the C5a-mediated neutrophil activation, resulting from activation of the alternative complement pathway, appears to be an effective therapeutic option and has been utilized in recent clinical trials.

Treatment of Granulomatosis with Polyangiitis and Microscopic Polyangiitis

The first goal of therapy for patients with ANCA-associated vasculitis is to induce a remission as quickly as possible, so that irreversible organ damage is minimized. To this end, early diagnosis and prompt application of an appropriate immunosuppressive regimen are crucial. At the same time the treatment plan needs to minimize the risk of treatment-related toxicity. Once remission has been induced, the second goal of therapy is to maintain remission with as few side effects as possible. These overarching principles apply to the therapy of both GPA and MPA.[46]

Remission Induction Therapy

Remission induction therapy is best tailored to the patient's degree of disease severity, extent, and acuity.[6,41] Rarely, patients who present with indolent GPA localized to the upper and/or lower airways and who are ANCA negative can be treated with trimethoprim/sulfamethoxazole at a dose of 160/800 mg twice daily. The mechanism of action of trimethoprim-sulfamethoxazole is unclear but possibly related to antimicrobial effects on *S. aureus*, the organism most frequently cultured from the nostrils of patients with GPA. It is also possible that this agent has immune-modulatory effects not shared by other antibiotics. Trimethoprim-sulfamethoxazole monotherapy should not be used in ANCA-positive patients, in the setting of glomerulonephritis, or in any other severe disease manifestation, and patients treated with trimethoprim-sulfamethoxazole need continued long-term observation, as some will later develop more severe disease manifestations requiring immunosuppressive therapy. It should be noted that this treatment option for patients with localized indolent ANCA-negative disease is not mentioned in the most recent guideline for the management of ANCA-associated vasculitis.[6]

Standard remission induction therapy for most patients categorized as having "limited" or "nonsevere" or "early-systemic" GPA consists of oral prednisone at doses of 0.5 to 1 mg/kg per day (generally not to exceed 80 mg/day) in combination with methotrexate with a target dose of 20 to 25 mg once a week.[50,51] This dose can be administered orally or subcutaneously. To minimize toxicity and the risk of *Pneumocystis* pneumonia (PCP), this immunosuppressive regimen should be supplemented by folic acid, 1 mg/day, and standard PCP prophylaxis. Azathioprine or mycophenolate mofetil are alternative options for patients who do not tolerate methotrexate.

For several decades, standard remission induction therapy for GPA or MPA patients with severe disease (also called "generalized" or "organ-threatening" disease) had consisted of oral prednisone in combination with oral cyclophosphamide at a dose of 2 mg/kg daily for 3 to 6 months.[52] One randomized controlled trial had shown that IV pulse therapy with cyclophosphamide consisting of three pulses of 15 mg/kg given 2 weeks apart followed by 15-mg/kg pulses given every 3 weeks for 6 months, was equally effective in inducing remission in severe GPA or MPA.[53] Based on results from a large, multicenter, randomized, double-dummy controlled trial that compared four once-weekly doses (375 mg/m^2 of body surface) of rituximab to standard oral cyclophosphamide for remission induction in severe ANCA-associated vasculitis, rituximab has now been approved for this indication by most regulatory agencies across the globe and is also included in therapeutic guidelines from multiple scientific societies.[6,54,55] The long-term follow-up of this study has shown that the efficacy of a single course of four once-weekly doses of rituximab (375 mg/m^2 of body surface) remains equivalent to continued standard daily oral immunosuppressive therapy with cyclophosphamide followed by azathioprine for 18 months.[46] These three remission induction regimens (IV or oral cyclophosphamide, rituximab) have been shown to be equivalent for newly diagnosed patients with severe GPA or MPA. Remission can be achieved in up to 90% of patients with either of these regimens. For patients presenting with a severe disease relapse, rituximab has been found to be superior to cyclophosphamide.[46,54,56] Rituximab was also found to be superior to cyclophosphamide for patients with PR3-ANCA, whereas for patients with MPO-ANCA no difference in efficacy was detected.[45] Rituximab is also the preferred agent for young patients in whom fertility needs to be preserved. The most recent guideline for the management of ANCA-associated vasculitis "conditionally recommend rituximab over cyclophosphamide for remission induction in patients with active, severe GP/MPA."[6] If oral cyclophosphamide is used, patients need to be monitored carefully to minimize the risk of bone marrow toxicity. The dose of cyclophosphamide should be adjusted in patients with impaired renal function, and the patient's complete blood counts need to be monitored at least biweekly for the duration of therapy. Optimal dosing with oral cyclophosphamide is achieved when the lymphocyte count is reduced but the total white blood count is maintained above 3500. To avoid bladder toxicity of cyclophosphamide, the entire dose is applied in the morning and patients are instructed to drink at least three liters of fluid per day.

In patients with rapidly progressive, fulminant disease, such as those presenting with alveolar hemorrhage or rapidly deteriorating renal function, IV methylprednisolone, 1000 mg per day for 3 to 5 days, may be initially necessary for effective control of inflammation.

More recently, given the role that the alternative complement pathway activation plays in ANCA-associated vasculitis, avacopan, a C5a receptor–blocking molecule, was tested in two phase 2 trials and one phase 3 and was found to be safe and effective in replacing glucocorticoids during induction of remission in patients with ANCA-associated vasculitis.[57–59] However, regulatory approval of this novel agent is still pending.

Role of Plasma Exchange in Remission Induction

If standard induction therapy does not generate the desired effects of controlling disease activity promptly, plasma exchange (PLEX) has been considered as an adjunct treatment modality. PLEX has long been proposed and used for patients with severe disease manifestations (severe progressive glomerulonephritis or diffuse alveolar hemorrhage) under the assumption that its effects are swift and supported by our understanding of the pathogenic role of ANCA. For two main reasons the application of PLEX has been considered and advocated especially for cases progressing to respiratory failure. First, analogous to anti–glomerular basement membrane disease (anti-GBM disease), PLEX allows the rapid removal of ANCA, which are thought to be pathogenic.[60] Second, a single retrospective uncontrolled cohort study of 20 patients with diffuse alveolar hemorrhage caused by MPA reported resolution of diffuse alveolar hemorrhage in all patients and only 1 death, outcomes far superior compared to previous reports of patients with pulmonary renal syndromes.[61] However, more recent evidence no longer supports the use of PLEX for patients with diffuse alveolar hemorrhage caused by ANCA-associated vasculitis.

The largest single center cohort study comprising 73 consecutive patients with diffuse alveolar hemorrhage due to GPA or MPA compared 32 patients treated with PLEX to 41 patients who did not receive PLEX.[62] There was no difference in hospital mortality, hospital length of stay, ICU length of stay, or days requiring respiratory support between patients who received PLEX compared with those who did not.[62] After adjusting for factors associated with disease severity affecting the likelihood of receiving PLEX and for the treatment choice of cyclophosphamide versus rituximab, the use of PLEX was not associated with achieving complete remission by 6 months (odds ratio [OR], 0.49; 95% confidence interval [CI], 0.12–1.95). A thorough review of the available literature also did not support a therapeutic benefit of PLEX in patients with diffuse alveolar hemorrhage secondary to ANCA-associated vasculitis.[62]

Finally, a large randomized controlled trial comprising 704 patients with ANCA-associated vasculitis with active renal disease or diffuse alveolar hemorrhage evaluated the efficacy of PLEX as adjunct to standard remission induction therapy (PEXIVAS trial).[63] This trial cohort included 191 patients with diffuse alveolar hemorrhage. There was no beneficial effect of PLEX on the primary outcome of death from any cause or end-stage kidney disease or on any of the secondary outcomes; there was also no evidence of interactions according to prespecified subgroups including diffuse alveolar hemorrhage with or without respiratory failure (oxygen saturation on room air $>85\%$ or $\leq 85\%$ or ventilated).[63] The only situation in which most experts seem to agree on the use of PLEX are patients who test positive for both ANCA and anti-GBM antibodies.[6]

Remission Maintenance Therapy

Once remission has been achieved, the prednisone dose is tapered gradually over the course of 1 to 6 months with the goal of complete discontinuation. The PEXIVAS trial also evaluated the role of a reduced dose of prednisone or prednisolone compared with standard dosing. At 6 months, the cumulative dose of oral glucocorticoids in the reduced-dose group was less than 60% of that in the standard-dose group. In addition, the reduced dose was noninferior to a standard dose regimen with respect to the risk of death or development of end stage kidney disease and resulted in a lower risk of serious infections in the first year of treatment.[63]

Patients with "nonsevere" disease should be maintained on methotrexate for remission maintenance.[51] Patients treated with cyclophosphamide for remission induction should be switched to either methotrexate or azathioprine for remission maintenance after 3 to 6 months of cyclophosphamide therapy.[64] Azathioprine is preferred in patients with any degree of renal insufficiency. Mycophenolate mofetil is an alternative for patients who cannot tolerate either methotrexate or azathioprine for remission maintenance. However, mycophenolate mofetil was found to be less effective than azathioprine for remission maintenance in one randomized controlled trial.[65] Remission maintenance therapy is continued for at least 18 to 24 months beyond achievement of remission, and longer in patients who are C-ANCA/PR3-ANCA positive or have suffered relapses. Early discontinuation of immunosuppressive therapy is associated with an unduly high relapse rate.

The need for remission maintenance therapy following remission induction with rituximab in newly diagnosed patients remains unclear. Over 18 months a single remission induction course of rituximab is as effective as oral cyclophosphamide followed by azathioprine, but PR3-ANCA-positive patients with GPA are at risk for relapse once peripheral blood B lymphocytes are reconstituted (after 6 to 12 months) and may benefit from long-term remission maintenance therapy.[66] Recent studies have evaluated the use of rituximab for maintenance of remission and have demonstrated that rituximab is effective and superior to azathioprine when utilized at a fixed dose of 500 mg every 6 months or when the therapy is individualized based on peripheral blood B lymphocytes and ANCA titers.[67,68]

Long-term remission maintenance therapy with trimethoprim-sulfamethoxazole beyond immunosuppression also may be beneficial. In one study, patients who received trimethoprim-sulfamethoxazole at a dose of 160/800 mg twice daily had a lower rate of disease relapse than those who received placebo.[69]

Treatment of Patients Refractory to Standard Therapy

About 10% of patients do not respond adequately to therapy with cyclophosphamide and fail to achieve remission. Over the last decade many cohort studies have found rituximab to be very effective in such patients, and rituximab has now become the de facto standard of care for refractory GPA.[56,70] These patients are particularly challenging, and other immunosuppressive drugs have been utilized with less success. Anti–TNF-α agents have not been shown to be effective in such patients. One large, multicenter, double-blind, placebo-controlled, randomized trial conducted in GPA did not demonstrate any benefit of adding etanercept to standard therapy.[64] Moreover, a higher frequency of malignancies was observed in the treatment arm compared with the control arm of that trial. All patients with malignancies had also received cyclophosphamide. For this reason, the use of etanercept in patients who have received cyclophosphamide is now strongly discouraged. Smaller, uncontrolled open-label studies with infliximab conducted in Europe have suggested some efficacy of that agent, but many complicated infections were observed in these patients.

Current guidelines recommend that patients who experience an inadequate response (refractory disease) to the original remission induction agent (rituximab or cyclophosphamide) be switched to the alternative agent.[6] Because of the prolonged B cell–depleting effect of rituximab this "switch" de facto represents the addition of cyclophosphamide to ongoing rituximab therapy.

Supportive Therapy

PCP still carries a mortality of up to 35%. Therefore, prophylaxis with trimethoprim-sulfamethoxazole is recommended for all non-sulfa-allergic patients with ANCA-associated vasculitis receiving immunosuppressive therapy including rituximab. Patients who have a sulfa allergy can be desensitized against the drug. Those who fail this approach or have other contraindications for the use of this drug should be given other agents for PCP prophylaxis. Patients receiving methotrexate for remission induction or maintenance should also receive PCP prophylaxis. This can be safely accomplished with trimethoprim-sulfamethoxazole at recommended doses for this purpose, provided that folic acid, 1 mg daily, is also given. Patients undergoing intense immunosuppression during the remission induction phase may also benefit from prophylactic antifungal therapy. Finally, every patient treated with glucocorticoids for ANCA-associated vasculitis should receive osteoporosis prophylaxis with calcium and vitamin D supplements and possibly bisphosphonates.

Treatment of Tracheobronchial Disease in GPA

The management of tracheobronchial involvement in GPA patients requires an individualized approach and goes beyond standard immunosuppressive therapy. Tracheobronchial inflammatory lesions may be more resistant to systemic immunosuppressive therapy than other disease manifestations. High-dose inhaled glucocorticoids are an integral part of therapy for patients with airway involvement, as they may facilitate the tapering of oral glucocorticoid dosing. Airway obstruction due to scarring may progress during otherwise successful immunosuppressive therapy, causing fixed airway obstructions that will only respond to dilation procedures or placement of silastic airway stents. Tracheo- or bronchomalacia with dynamic airway collapse also may benefit from airway stent placement or from continuous positive airway pressure treatment. Tracheobronchial inflammation of GPA is often associated with persistent or recurrent airway infections with *S. aureus* or *Pseudomonas aeruginosa*. These should not be dismissed as "colonizers" but treated with antibiotics according to antimicrobial susceptibility results, as these infections may play a pathogenic role as "antigenic drivers" of the autoimmune inflammation. Finally, as silent gastroesophageal reflux may induce or aggravate airway inflammation, patients should be instructed in the use of dietary and behavioral reflux precautions in addition to acid-blocking therapy.

Treatment of Interstitial Lung Disease and ANCA with or without MPA

The current literature supports the following practical management approach to patients with ILD and MPO-ANCA with or without overt signs of MPA.[72] Patients with any ILD and active MPA should receive standard remission induction immunosuppressive therapy for severe MPA, usually consisting of glucocorticoids in combination with either cyclophosphamide or rituximab.[41] Patients with a positive MPO-ANCA and an ILD characterized by radiographic changes of NSIP or other inflammatory features such as bronchiolitis may need further diagnostic testing to rule out signs of active vasculitis, particularly diffuse alveolar hemorrhage. Once ruled out, such patients should be given a trial of glucocorticoids together with either azathioprine or mycophenolate mofetil as glucocorticoid-sparing and maintenance agent. Patients with usual interstitial pneumonia (UIP) pattern and positive MPO-ANCA but without signs of vasculitis need to be monitored carefully for the future development of vasculitis but should not receive immunosuppressive therapy, as this has been shown to increase the mortality of patients with UIP.[73] These patients should be offered antifibrotic therapy.

■ Treatment of Eosinophilic Granulomatosis with Polyangiitis

Even though mortality of EGPA is lower than that of GPA or MPA, the management of EGPA remains a challenge. The management concepts for EGPA are modeled after those for GPA and MPA. Patients should benefit from a multidisciplinary evaluation at a center of excellence and expertise with the disease. As all treatment aims to minimize tissue damage caused by disease activity or treatment toxicity, the diagnosis should be established as early as possible, the inflammation needs to be controlled as effectively as possible, and drug toxicities including those associated with cumulative glucocorticoid exposure should be prevented as best as possible. For EGPA this means to effectively target eosinophils and their activity while at the same time minimizing glucocorticoid exposure by preventing disease relapses and optimizing the management of chronic asthma and rhinosinusitis.[74,75]

Treatment choices for EGPA are stratified by disease severity. "Severe" disease is defined as life- or organ-threatening, comprising heart, gastrointestinal, kidney and CNS involvement as well as mononeuritis multiplex and diffuse alveolar hemorrhage. Other disease manifestations and organ involvement including nose or sinus disease, asthma and eosinophilic pulmonary infiltrates, or pulmonary nodules or skin vasculitis are considered "nonsevere" disease. The term *refractory disease* refers to disease activity that flares during glucocorticoid tapers or requires doses of 7.5 mg of prednisone or greater to control disease activity.

Glucocorticoids are used as primary remission induction agent for all patients. There are no clinical trials that provide clear guidance regarding glucocorticoids in EGPA. The reports from the French Vasculitis Study Group are difficult to interpret with respect to this disease, because patients with EGPA were not separated from those with polyarteritis nodosa and MPA, two diseases with distinct clinical manifestations, pathophysiology, and prognosis.[76,77] Yet, these studies suggest that it is appropriate to treat EGPA according to the principles applied to the management of GPA and MPA. In patients with "nonsevere" disease, standard disease-modifying drugs like azathioprine, methotrexate, or mycophenolate mofetil are customarily used as glucocorticoid-sparing agents if the prednisone dose cannot be reduced down to 10 mg per day without relapsing disease activity.[78] For patients with "severe" disease manifestations, additional immunosuppressive agents such as cyclophosphamide or rituximab are given in conjunction with glucocorticoids for induction of remission. Cyclophosphamide is the preferred agent for heart, gastrointestinal, peripheral, and central nervous system involvement. When cyclophosphamide is used for induction of remission, it should be replaced when remission has been achieved after 4 to 6 months by another glucocorticoid-sparing agent such as azathioprine for maintenance of remission.[78]

Rituximab has also been used for patients with EGPA, particularly if patients are MPO-ANCA positive and present with predominant small vessel vasculitis disease manifestations including kidney involvement or the rare occurrence of DAH.[79,80] Rituximab has also been shown to allow significant glucocorticoid dose reductions in patients with EGPA, even when glucocorticoids were primarily used for the control of severe chronic asthma.[80,81]

Most recently, biologic therapy targeting interleukin 5 (IL-5), which is elevated in EGPA and known to induce the proliferation and maturation of eosinophils, has shown promise as an effective glucocorticoid-sparing approach in EGPA. In a large, randomized, double-blind, placebo-controlled, phase 3 trial, mepolizumab demonstrated significant and clinically relevant glucocorticoid-sparing effects in the majority of patients with EGPA.[75,82] However, patients with severe eosinophil-driven or vasculitic disease manifestations were excluded from the trial, and consequently the effect of IL-5 targeted therapy in these circumstances remains unclear.[82]

In a recent phase 2 study, benralizumab, a monoclonal antibody that targets the IL-5 receptor α subunit, showed safety and efficacy in the treatment of EGPA.[83] A randomized, double-blind, double dummy–controlled, phase 3 trial comparing benralizumab to mepolizumab is ongoing. Refractory disease and disease dominated by difficult-to-control eosinophilic inflammation may respond to interferon α (IFN-α) therapy.[84] However, continued long-term IFN-α therapy may be necessary, and this treatment carries the risk of substantial toxicity.

OTHER DISORDERS PRESENTING WITH PULMONARY VASCULITIS

Below we consider a wide variety of entities characterized by pulmonary vasculitis, including giant-cell arteritis, Takayasu arteritis, polyarteritis nodosa, Behçet disease, idiopathic pauci-immune pulmonary capillaritis, and systemic lupus erythematosus, among others.

■ Giant-Cell Arteritis

Giant-cell arteritis (GCA) is a generalized inflammatory disorder involving large- and medium-sized arteries.[85] GCA is the most common form of vasculitis in the northern hemisphere and affects predominantly elderly patients. It is often associated with polymyalgia rheumatica and is considered a systemic inflammatory syndrome often presenting with nonspecific systemic symptoms such as low-grade fever, malaise, and weight loss. New-onset headache, scalp tenderness, facial pain, or jaw claudication are the most common symptoms of GCA. Transient or permanent vision loss affects 20% and 10% of patients, respectively. Temporal arteries are often palpably tender or nodular, and pulses are decreased. Markedly elevated markers of inflammation—erythrocyte sedimentation rate (ESR) and C-reactive protein—are found in most if not all patients. Granulomatous inflammation of the wall of affected vessels is the histopathologic finding of temporal artery biopsies.

Respiratory symptoms have been reported in up to 25% of patients. Cough, hoarseness, and throat pain usually resolve promptly with prednisone therapy.[86] Chest roentgenograms and pulmonary function tests rarely show abnormalities attributable to the disease. Occasionally respiratory symptoms are the initial manifestations of giant-cell arteritis. Therefore, this possibility should be considered in any elderly patient with new onset of cough, hoarseness, or throat pain without other identifiable cause, and it is reasonable to measure the ESR in such patients. Isolated cases with pleural effusion or multinodular pulmonary lesions have also been reported in giant cell arteritis. Such cases are difficult to interpret. Particularly in the latter situation, GPA should be considered in the differential diagnosis, because it may also present with temporal arteritis. Glucocorticoid-sparing agents such as methotrexate are recommended for selected patients with giant-cell arteritis. More recently, high-quality evidence has shown that tocilizumab (humanized monoclonal antibody against the interleukin 6 receptor) is an effective glucocorticoid-sparing agent in these patients and has been approved for this condition.[87,88]

■ Takayasu Arteritis

Takayasu arteritis (TAK) is a large vessel vasculitis predominantly affecting the aorta and its major branches, usually in young patients.[85] Gender distribution and preferentially affected vascular territories vary in different parts of the world.[89] TAK is a chronically relapsing disease that may present with nonspecific constitutional symptoms, low-grade fever, and arthralgias and myalgias. Variable pulses in affected vascular territories are typical exam findings. Claudication, renovascular hypertension, pulmonary hypertension, and ischemia in distal tissues are disabling consequences.[89]

TAK affects large- and medium-size pulmonary vessels in the form of a unique arteriopathy.[90] The inflammatory infiltrate of the vessel walls consists predominantly of lymphocytes, and giant cells are a prominent feature of the inflammation. Pulmonary artery stenosis and occlusion are the result of progressive defects in the outer media and ingrowth of granulation tissue–like capillaries, thickening of the intima, and proliferation of subendothelial smooth muscle cells; these changes can also cause pulmonary hypertension of variable severity in up to one-half of all patients. The involvement of pulmonary arteries is common but often asymptomatic. It is detectable by conventional angiography, perfusion scan, or magnetic resonance angiography. CT may show areas of mosaic attenuation as a result of regional hypoperfusion, subpleural reticulolinear changes, and pleural thickening. Chest roentgenograms are usually normal. Fistula formation between pulmonary artery branches and bronchial arteries, as well as nonspecific inflammatory interstitial lung disease, also have been reported.

Therapy for TAK consists primarily of immunosuppression with glucocorticoids. Other immunosuppressive agents, including methotrexate, are used as in conjunction with glucocorticoids for remission induction and as glucocorticoid-sparing agents for remission maintenance. Unfortunately, many patients relapse when the glucocorticoid dose is reduced below 15 mg daily. There are no controlled studies with anti–TNF-α agents such as infliximab in TAK. Observational data, mostly with infliximab, suggest that these agents improve event-free survival and decrease disease flares and organ damage. Treatment with tocilizumab targeting interleukin 6 has also been reported to be of benefit and is recommended for patients with relapsing disease.[87,88] In addition, small case series have reported beneficial effects with rituximab.[91] Vascular bypass or stenting procedures may be beneficial in severe disease, but their long-term benefits remain unclear.

■ Classic Polyarteritis Nodosa

Since its formal separation from microscopic polyangiitis, this form of vasculitis affecting predominantly medium-sized vessels is diagnosed rarely. Because it does not affect capillaries, it does not cause either glomerulonephritis or diffuse alveolar hemorrhage. However, there are rare case reports of classic polyarteritis nodosa with lung hemorrhage caused by involvement of the bronchial or bronchiolar arteries.[92] Most cases of classic polyarteritis nodosa diagnosed today are associated with viral infections, specifically hepatitis B and C. Consequently, antiviral therapy plays a prominent role in the management of such cases in addition to immunosuppression. Classic polyarteritis nodosa is far less likely to relapse than microscopic polyangiitis, and therefore can generally be treated with a shorter course of immunosuppression.

■ Behçet Disease

Behçet disease is a rare, chronically relapsing, systemic inflammatory disorder characterized by aphthous oral ulcers and at least two or more of the following: aphthous genital ulcers, uveitis, cutaneous nodules or pustules, or meningoencephalitis. Respiratory manifestations are common in Behçet disease and include cough, hemoptysis, chest pain, and dyspnea.[93] Hemoptysis is often massive and fatal. The vasculitis of Behçet disease is immune complex–mediated and may affect vessels of all sizes. If the veins are affected, secondary thrombosis with major venous occlusion can occur. This type of thrombosis may not be preventable by anticoagulation, but the use of aspirin 81 mg/day has been advocated. Massive hemoptysis is the result of destruction of the elastic lamina of pulmonary arteries leading to the characteristic aneurysm formation, secondary erosion of bronchi, and arterial–bronchial fistulae. Pulmonary artery aneurysms are detectable by CT or MR angiography, and pulmonary angiography is no longer necessary. Recurrent pneumonia as well as bronchial obstruction as a consequence of mucosal inflammation also have been described.

Therapy of the underlying disease consists of immunosuppression. Prednisone alone may not be sufficient to control the vasculitis. The addition of other drugs, such as colchicine, chlorambucil, methotrexate, cyclosporine, or azathioprine, is recommended. The addition of azathioprine or cyclophosphamide to glucocorticoids has resulted in resolution of pulmonary aneurysms. More recently, observational studies have shown that TNF-α inhibitors seem to be a highly effective option for remission induction of refractory Behçet disease with vascular involvement with acceptable safety data.[94] Once pulmonary arteritis has been identified in these patients, anticoagulation should be avoided. The prognosis of pulmonary involvement is poor. About one-third of patients die within 2 years of developing pulmonary involvement, most from fatal pulmonary hemorrhage. Embolization therapy may be used as treatment and prevention of hemorrhage from pulmonary artery aneurysms.

■ Idiopathic Pauci-immune Pulmonary Capillaritis

Idiopathic pauci-immune pulmonary capillaritis is a rare diagnosis of exclusion.[95,96] The diagnosis is based on the histopathologic confirmation of capillaritis in the absence of (1) a defined systemic disease process with extrapulmonary organ involvement, (2) specific circulating autoantibodies, and (3) detectable immune deposits on the lung biopsy specimen. This isolated pauci-immune pulmonary capillaritis is histopathologically indistinguishable from that of ANCA-associated vasculitis. Despite the lack of clear evidence of an immune etiology, the cases reported to date have responded to immunosuppressive therapy following the principles of the management of ANCA-associated vasculitis with diffuse alveolar hemorrhage—that is, remission induction therapy with the combination of glucocorticoids and cyclophosphamide or rituximab.[95–97] Since disease relapses have been described, remission maintenance therapy should be considered for individual cases.

■ Systemic Lupus Erythematosus and Other Collagen Vascular Disorders

The disease manifestations of systemic lupus erythematosus (SLE) are highly variable. Pulmonary capillaritis leading to diffuse alveolar hemorrhage is rare in patients with SLE. However, it represents one of the most serious complications of the disease. In contrast to the pauci-immune pathology of ANCA-associated vasculitis, prominent immune complex deposits can be detected by direct immunofluorescence in the affected tissue of patients with SLE (Fig. 74-18). Hence, the development of pulmonary capillaritis in SLE is thought to be immune complex mediated.

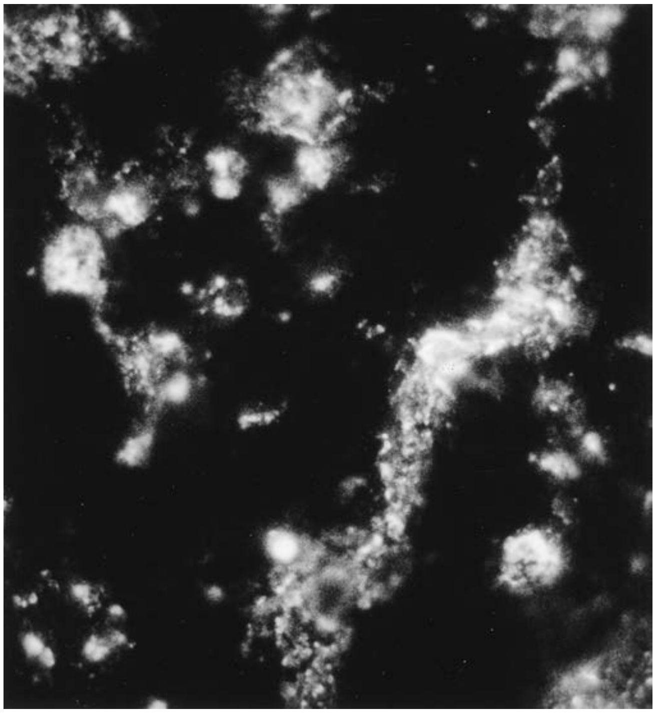

Figure 74-18 Lung biopsy of a patient with lupus erythematosus and alveolar hemorrhage showing so-called lumpy, bumpy deposition of immune complexes as demonstrated by direct immunofluorescence.

The onset of diffuse alveolar hemorrhage in patients with SLE is usually abrupt, and it is seldom the first sign of SLE. In the overwhelming majority of patients, the rapid development of pulmonary infiltrates is associated with fever. Hemoptysis may be absent in up to one-half of patients. Consequently, the differentiation of diffuse alveolar hemorrhage from infection may be difficult in patients with SLE and may require a diagnostic bronchoalveolar lavage. Mechanical ventilation, infection, and cyclophosphamide therapy were identified as negative prognostic factors in one cohort.[98] However, no multivariate analysis was performed in that cohort study, and these factors may simply identify patients with more severe disease. The reported mortality from diffuse alveolar hemorrhage in SLE varies widely, between 0% and 90%. Treatment mainly consists of glucocorticoids and cyclophosphamide.[99,100] The use of PLEX has been suggested, but its benefit remains unproved.[100]

In a recent systematic review of patients with SLE presenting with diffuse alveolar hemorrhage (174 episodes of alveolar hemorrhage in 140 patients), the overall survival was 61%, corticosteroids were nearly universally used therapeutically, cyclophosphamide was used in 55% of patients, and PLEX was used in 31% of the patients but did not appear to be associated with survival.[101] Rituximab use in these patients has been described in case reports with conflicting results.[100]

Respiratory complications are very common in all other types of collagen vascular or connective tissue disorders. However, pulmonary capillaritis presenting as diffuse alveolar hemorrhage is rare. Isolated cases have been reported with polymyositis, rheumatoid arthritis, and mixed connective tissue disease. Consequently, serologic testing performed as part of an evaluation of diffuse alveolar hemorrhage should include studies aimed at the identification of these potential underlying disease entities.

■ Antiphospholipid Syndrome

Antiphospholipid syndrome is defined by arterial and venous thromboses, and/or recurrent miscarriages occurring in patients with antiphospholipid antibodies (anticardiolipin antibodies, lupus anticoagulant, or both). If antiphospholipid syndrome occurs in the context of another autoimmune disease, malignancy, or drug exposure, it is labeled secondary antiphospholipid syndrome. In the absence of other coexisting disorders, it is considered primary. Hypercoagulability can cause pulmonary embolism and infarction, pulmonary microthrombosis, and pulmonary arterial thrombosis with secondary pulmonary hypertension as consequence (i.e., chronic thromboembolic pulmonary hypertension). However, primary pulmonary hypertension also has been reported in antiphospholipid syndrome. Acute respiratory distress syndrome (ARDS) is another possible complication of catastrophic antiphospholipid syndrome. Antiphospholipid syndrome can also be complicated by diffuse alveolar hemorrhage, presenting with cough, dyspnea, fever, and bilateral pulmonary infiltrates. Because of this nonspecific clinical presentation and the lack of hemoptysis in more than one-half of the reported antiphospholipid syndrome patients with alveolar hemorrhage, early performance of bronchoalveolar lavage may help to distinguish alveolar hemorrhage from ARDS. Tissue necrosis from microthrombosis as well as pulmonary capillaritis have been implicated as the cause of alveolar hemorrhage in antiphospholipid syndrome. As in SLE, the capillaritis of antiphospholipid syndrome appears to be immune complex–mediated.

Most patients respond to glucocorticoids.[102,103] Yet, the coexistence of thrombosis and capillaritis with alveolar hemorrhage represents a therapeutic dilemma, as anticoagulation may need to be interrupted to control the hemorrhage. The largest case series of primary antiphospholipid syndrome–associated diffuse alveolar hemorrhage demonstrated a very poor prognosis with limited therapeutic options that included immunosuppression. Agents such as azathioprine or mycophenolate mofetil, in combination with glucocorticoids, failed to control disease activity.[102] However, cyclophosphamide or rituximab were associated with the highest likelihood of remission induction and should be considered early. This case series also reported the use of PLEX in three patients, with no response observed in any of these patients. However, others have reported improved outcomes with the use of early PLEX in addition to immunosuppressive therapy.[104]

■ Cryoglobulinemic Vasculitis

Diffuse alveolar hemorrhage has been reported as a rare complication of cryoglobulinemic vasculitis with an associated poor prognosis. Among 125 patients hospitalized with cryoglobulinemia over a 23-year time period, 4 patients developed alveolar hemorrhage.[105] These were analyzed in conjunction with 6 additional cases from the literature reported to that date. Of these 10 patients, 9 also had glomerulonephritis, and 6 deaths were attributed to the diffuse alveolar hemorrhage.[105] Treatment consisted of aggressive immunosuppression in various combinations with or without PLEX.[105]

■ Anti–glomerular Basement Membrane Disease

Historically the syndrome of diffuse alveolar hemorrhage and glomerulonephritis has been called Goodpasture syndrome. To avoid any confusion and reflect our understanding of the pathogenesis of the disease, the 2012 Chapel Hill Consensus conference recommended avoidance of the eponym and the use of the term anti-GBM disease for alveolar hemorrhage or necrotizing glomerulonephritis caused by autoantibodies directed against the NC1-domain of the α3 chain of basement membrane collagen type IV.[6] Autoantibodies can only access this epitope in the basement membranes of kidneys and lungs. Diffuse alveolar hemorrhage is common in anti-GBM disease but is thought to require an additional inhalational injury, particularly smoking, for the development of the pulmonary manifestation of this disease. Isolated alveolar hemorrhage in the absence of renal disease is rare in anti-GBM disease. The finding of circulating anti-GBM autoantibodies in the serum may facilitate the early implementation of appropriate therapy. However, methods used for their detection are of highly variable sensitivity and specificity, and a definitive diagnosis depends on the documentation of linear anti-GBM deposits in the kidney or lung (Fig. 74-19).

In most patients, tissue from the kidney is more easily accessible for histopathologic evaluation than lung tissue. Anti-GBM disease is arguably not a vasculitis. Bland pulmonary hemorrhage is the most frequently described histopathologic pattern in diffuse alveolar hemorrhage associated with anti-GBM disease. However, capillaritis as a secondary histopathologic feature has been encountered in some patients.

Early implementation of immunosuppressive therapy with high doses of glucocorticoids in conjunction with PLEX is the key to a favorable outcome in patients with anti-GBM disease.[106] Cyclophosphamide or rituximab can be added to prevent subsequent rebound antibody formation.[106–108] The use of extracorporeal membrane oxygenation has been reported as salvage therapy for isolated cases of severe diffuse alveolar hemorrhage caused by anti-GBM disease.[109,110]

■ IgA Vasculitis (Henoch-Schönlein)

Henoch-Schönlein purpura has been renamed as *IgA vasculitis (Henoch-Schönlein)* at the 2012 Chapel Hill Consensus Conference to reflect the evolving understanding of its pathogenesis. The disease affects predominantly children and young adults and presents with fever, purpura, large joint arthralgias and arthritis, gastrointestinal symptoms, and usually self-limited and mild proliferative and necrotizing glomerulonephritis.[1] The diagnosis is based on characteristic IgA deposits detected in skin- or kidney biopsies. Pulmonary manifestations in IgA vasculitis are rare. IgA deposits along the pulmonary capillary walls, analogous to those found in vessels of the skin and glomeruli of affected kidneys, are pathognomonic features of IgA vasculitis, detectable by direct immunofluorescence. Diffuse alveolar hemorrhage has been reported as the cause of several deaths in patients with IgA vasculitis;[111] its presence in IgA vasculitis should thus warrant aggressive immunosuppressive therapy.

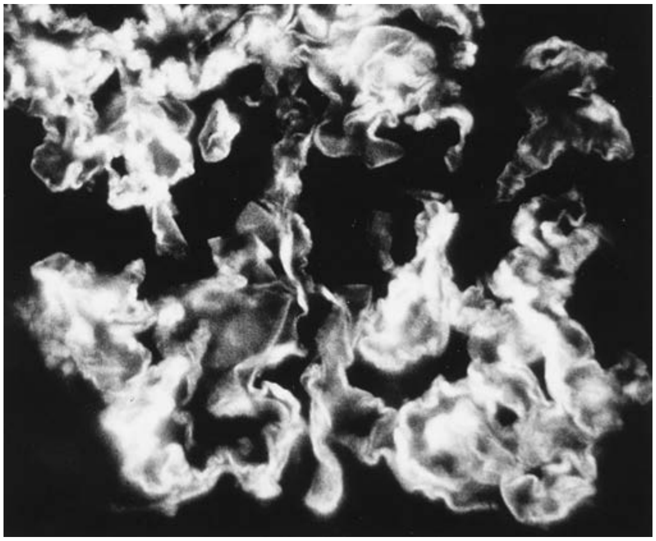

Figure 74-19 Kidney biopsy of a patient with anti–glomerular basement membrane (GBM) disease showing linear immunofluorescence of the glomerular basement membrane due to fixation of IgG anti-GBM antibodies.

■ Drug-Induced Vasculitis

The list of drugs described in association with vasculitis includes a long list of therapeutic agents as well as drugs of abuse.[112] The clinical spectrum of drug-induced vasculitis ranges from isolated and mild vasculitis of the skin to severe multiorgan system disease. Small- to medium-sized vessels are usually affected. Based on clinical manifestations, drug-induced vasculitis cannot be distinguished from the primary vasculitis syndromes.

The following drug-induced syndromes merit special attention. First, a variety of drugs including propyl-thiouracil, D-penicillamine, hydralazine, sulfasalazine, minocycline, and allopurinol can induce an ANCA-associated vasculitis. Pulmonary capillaritis as a manifestation of an ANCA-associated vasculitis induced by these agents is well documented. Drug-induced ANCA-associated vasculitis should be treated with immunosuppression according to the principles for primary ANCA-associated vasculitis. However, once the offending drug has been eliminated, the likelihood of a relapse seems low.

The use of all-*trans*-retinoic acid in acute promyelocytic leukemia can cause a syndrome of fever, leukocytosis, fluid retention, hemorrhage, thrombosis, and organ failure. Pulmonary complications of this syndrome are frequent, and pulmonary capillaritis has been reported in this context.

Some chronic nasal cocaine abusers develop severe midline destructive lesions. In its early stage, such a lesion is clinically and histopathologically difficult to differentiate from limited GPA, particularly in patients who do not volunteer the history of abuse.[113]

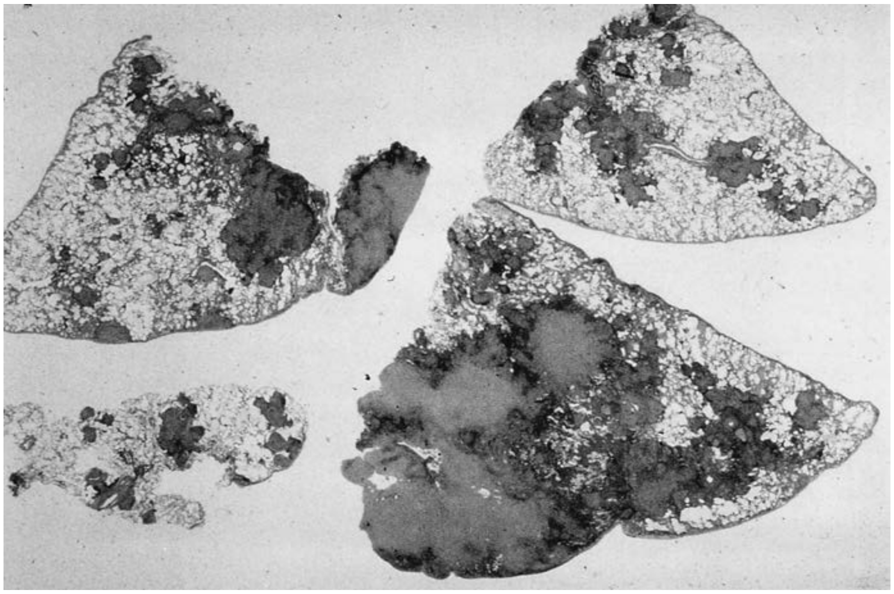

Figure 74-20 Low-power photomicrograph of lung revealing coalescing necrotizing granulomas in a patient with necrotizing sarcoid granulomatosis.

The presence of ANCA reacting with human neutrophil elastase (HNE) appears to be an immunologic marker separating patients with cocaine-induced midline destructive lesions from those with GPA.[114]

More recently, levamisole has become a common adulterant of cocaine.[115,116] Levamisole is a polyclonal B cell–stimulating agent that can induce a variety of autoantibodies including antigranulocyte antibodies, antiphospholipid antibodies, and ANCA. The ANCA reactivity is directed against multiple target antigens including MPO, PR3, and HNE.[115,116] The clinical picture of patients exposed to levamisole can mimic systemic vasculitis.

■ Pulmonary Capillaritis after Lung Transplantation

Several cases of pulmonary capillaritis after lung transplantation have been described in the literature. In the largest case series that included 40 episodes of capillaritis in 35 patients, the presentation of posttransplant capillaritis was similar to that of acute cellular rejection but with a distinct histologic pattern and a dissimilar response to corticosteroid therapy.[117] Pulmonary capillaritis is now believed to be a manifestation of antibody-mediated acute rejection and typically occurs in association with development of donor-specific alloantibodies. Early histologic diagnosis and aggressive immunosuppression, in conjunction with PLEX, is employed to control the inflammatory activity and prevent relapses.

■ Necrotizing Sarcoid Granulomatosis

Vasculitis is a prominent histopathologic feature of necrotizing sarcoid granulomatosis. The disease is usually limited to the lungs. The characteristic pulmonary nodules are bilateral and may be an incidental finding in asymptomatic patients. Alternatively, patients may complain of cough, dyspnea, and/or sputum production. Generalized constitutional symptoms occur rarely. The differential diagnosis of necrotizing sarcoid granulomatosis includes primarily infectious processes. Special sputum and tissue stains and cultures should always be obtained to exclude mycobacterial or fungal disease. Clinically, these patients are difficult to differentiate from "nonsevere" GPA. Histopathologically, there are characteristic necrotizing epithelioid granulomas that may form aggregates (Fig. 74-20). In contrast to GPA, these granulomas are well circumscribed. Vasculitis is a central histopathologic feature of necrotizing sarcoid granulomatosis. Liebow originally described three types of vasculitis: an epithelioid-granulomatous form, a form reminiscent of giant-cell arteritis with prominent histiocytes and multinucleated giant cells in the inflammatory infiltrate of the vessel wall, and a lymphocytic form lacking granuloma formation and giant cells. The separation from sarcoidosis remains controversial. Yet, the extensive vasculitis and necrosis seen in necrotizing sarcoid granulomatosis are unusual for sarcoidosis. The chest roentgenographic appearance of pulmonary nodules, or masses and pleural involvement, are also atypical for sarcoidosis. Finally, extrapulmonary involvement has only rarely been documented in necrotizing sarcoid granulomatosis.

It is debatable whether necrotizing sarcoid granulomatosis should be included with the systemic vasculitides. Most authors would argue against this inclusion because of its limitation to the lungs and good prognosis (spontaneous remission may occur). Therapeutically, necrotizing sarcoid granulomatosis is approached in similar fashion to chronic pulmonary sarcoidosis, with oral glucocorticoid therapy representing the primary treatment of choice.

CHAPTER 75

Pulmonary Arteriovenous Malformations

Tyler J. Peck
Josanna M. Rodriguez-Lopez

INTRODUCTION

In the normal pulmonary circulation, blood leaves the right ventricle of the heart via the pulmonary artery, and the entire blood volume is routed to the pulmonary capillary bed adjacent to alveoli, allowing for gas exchange. The normal diameter of blood vessels making up the pulmonary capillary bed is approximately 6 μm.[1] After drainage from the pulmonary capillaries, the blood then returns to the heart via the pulmonary veins. Pulmonary arteriovenous malformations (PAVMs) are abnormal vascular connections between pulmonary arteries and pulmonary veins, preventing exposure of blood to normal pulmonary capillaries and many times leading to hypoxemia due to shunting of deoxygenated blood into the pulmonary venous system and into the systemic circulation. Additionally, the size of these abnormal connections is typically larger than the size of pulmonary capillaries, allowing for transmission of particles in the blood stream (e.g., venous thromboemboli) from the venous circulation into the arterial circulation, leading to complications like stroke or septic emboli. Pulmonary AVMs are commonly aneurysmal and can frequently be seen macroscopically on advanced imaging (e.g., CT angiography).

Pulmonary AVMs were first described by Churton in 1897 in an autopsy case report of a 12-year-old boy with hemoptysis, epistaxis, and edema.[2] In the early 20th century, PAVMs were found to be associated with hereditary hemorrhagic telangiectasia[3] (HHT; also known as Osler–Weber–Rendu syndrome), a genetic vascular disorder manifesting with mucocutaneous telangiectasia and AVMs of various organ systems, including the lung. It is now known that at least 60% to 70% of PAVMs are associated with HHT,[4,5] although some reports indicate rates of up to 95%.[6]

In this chapter, we discuss the epidemiology, pathobiology, and etiologies of pulmonary AVMs, clinical manifestations and diagnostic evaluation of these abnormalities, associated complications, and management options.

EPIDEMIOLOGY OF PULMONARY AVMs

PAVMs are generally uncommon, occurring in only 3 cases among 15,000 consecutive autopsies performed at Johns Hopkins Hospital[7] (translating to a disease prevalence of 0.02%). However, disease frequency has been found to be higher in populations of patients with HHT—reported in case series as ranging from 17%[8] to 48%.[9] PAVMs occur about twice as often in women compared with men,[4,10] although a majority of cases identified in newborns occur in males.[11]

Disease frequency of HHT varies between populations, estimated at 1 in 8000 in a northern Japanese population,[12] 1 in 6000 in European populations,[13] and 1 in 16,500 the U.S. state of Vermont.[5] A study of U.S. insurance claims data found a disease prevalence of 0.33 cases per 10,000 individuals.[14] However, a few geographically isolated populations show higher prevalence, likely due to founder events; for example, 1 in 1331 individuals was found to be affected in the Afro-Caribbean population of the Netherlands Antilles.[15] These statistics likely underestimate the true disease prevalence of this rare disease that may be underrecognized.

PATHOLOGY

PAVMs are structurally made up of three components: a vascular aneurysmal sac, a feeding artery (or arteries), and a draining vein (or veins). A majority of PAVMs have a single feeding artery with a single draining vein (approximately 80%[16,17]) and are thus considered "simple." However, some PAVMs are categorized as "complex" given their more complicated anatomy with two or more feeding arteries and/or draining veins.

The aneurysmal sac of PAVMs typically has paper-thin walls made up by a thin-walled vascular channel lined with endothelium and scant surrounding connective tissue stroma that does not have communication with surrounding lung tissue.[7] The vascular channel may be made up of a large single sac, a plexiform mass of dilated vascular channels, or a dilated and often tortuous communication between artery and vein.[18,19] These dilated vascular channels gradually increase in size over time[8,20] and acutely with pregnancy.

PAVMs are most commonly found in the lower lobes of the lung, attributed to increased hydrostatic pressure in the dependent portions of the lung.[16] In a case series detailing pathologic anatomy in 350 patients with PAVMs, 75% of PAVMs were unilateral, 36% had multiple lesions, and half of those with multiple lesions had bilateral disease.[18,19] PAVM sacs typically range in diameter from microscopic up to 5 cm, although there are many case reports of larger PAVMs in select cases.[19]

A small subset of patients have diffuse PAVMs, a rare subtype associated with diffuse lung involvement, increased risk of complication, and worse prognosis compared to other patients with PAVM[21,22] (Fig. 75-1).

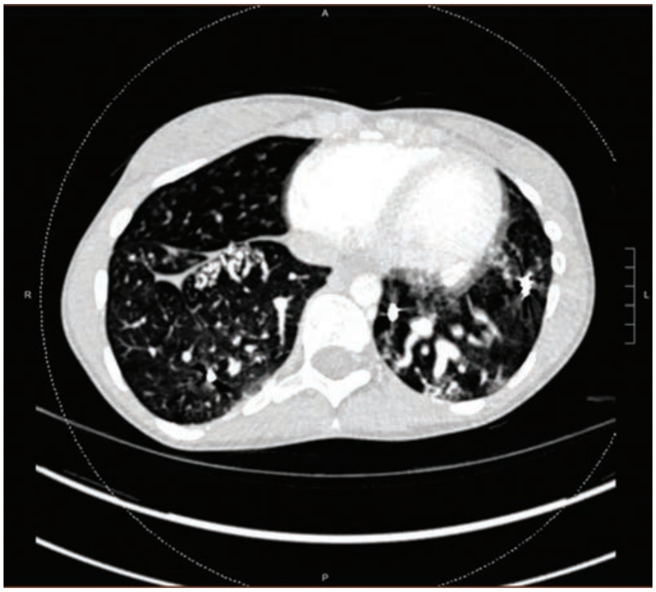

Figure 75-1 Diffuse, bilateral pulmonary AVMs in a 20-year-old woman without diagnosis of heredity hemorrhagic telangiectasia, with progression of PAVMs following prior coil embolization.

TABLE 75-1 Identified Genes Associated with Hereditary Hemorrhagic Telangiectasia and Pulmonary Arteriovenous Malformations

Gene—Protein	Chromosomal Location	Function	HHT Form	Frequency of Pulmonary AVMs
ENG—endoglin[123,124]	9q34	Transforming growth factor β (TGF-β)-binding protein found on endothelial cells	HHT1	85%[125]
ACVRL1 (also known as *ALK1*)—activin A receptor, type II–like 1[126]	12q13	Type I cell-surface receptor for the TGF-β superfamily of ligands	HHT2	35%[125]
SMAD4 (also known as *MADH4*)—SMAD family member 4[34,127,128]	18q21	Downstream mediator of TGF-β signaling, acting as a transcription factor	Juvenile polyposis/HHT syndrome (JPHT)	50%[127]

GENETICS AND PATHOGENESIS

Most PAVMs are congenital and are associated with HHT, an autosomal dominant disease that primarily affects blood vessels. HHT is associated with mutations in *ENG*, *ACVRL1*, or *SMAD4* (Table 75-1). However, approximately 15% of patients with a clinical diagnosis of HHT do not have identified mutations in these genes, suggesting the presence of additional causative mutations for HHT.[23–26] Additional HHT-associated genes have been isolated in select cases lacking mutations in the aforementioned identified genes, but these are less well understood and are under investigation.[27,28]

ENG, *ACVRL1*, and *SMAD4* gene products play various roles in the transforming growth factor β (TGF-β) signaling pathway, which has been implicated in angiogenesis and vascular remodeling.[25] TGF-β signaling regulates endothelial cell function through either stimulation or inhibition of their proliferation.[25] Animal studies have shown that *endoglin* and *ALK1* knockout mice die mid-gestation due to defective vascular development including excessive fusion of capillaries, dilated major blood vessels, abnormal differentiation and localization of vascular smooth muscle cells, and development of AVMs.[29–33] Knockout animals for *SMAD4* also have increased formation of AVMs, endothelial cell proliferation, and disruption of artery-vein identity.[34] ACVRL1 (or ALK1, as this gene product is commonly known) serves as a type 1 receptor for the TGF-β/BMP superfamily, and endoglin (ENG) is a coreceptor that promotes TGF-β signaling via the ACVRL1 receptor. This receptor complex has kinase activity that activates a SMAD signaling cascade, leading to the activation and translocation of transcription factors into the nucleus where they function to activate or repress transcription of specific target genes that modulate vascular responses.[25,35] SMAD4 is an intracellular mediator of TGF-β signaling as part of the SMAD signaling cascade, forming a heteromeric complex with other SMAD molecules activated by cell-surface receptors and translocating to the nucleus to modulate gene expression via endothelial-specific transcriptional modulators[25,34] (Fig. 75-2).

Analysis of mutations in *ENG* and *ACVRL1* in patients with HHT shows loss-of-function mutations in nearly all cases.[26] It remains less clear why vascular abnormalities occur in specific sites in the various phenotypes of HHT, likely owing to haploinsufficiency[36–38] or somatic mutations leading to biallelic loss of gene function.[39]

The pathogenesis of PAVMs is not clearly understood aside from its foundation in aberrant vascular development and remodeling associated with disruptions in the TGF-β signaling pathway as described above. Hypotheses regarding development of PAVMs include a defect in terminal arterial loops allowing dilation of thin-walled capillary sacs,[40] incomplete resorption of vascular septae separating the arterial and venous plexuses that normally anastomose during fetal development,[41] and failure of capillary development during fetal development.[41]

ETIOLOGIES OF PULMONARY AVMs

The most common disease associated with PAVMs is HHT, primarily due to mutations in *ENG*, *ACVRL1*, or *SMAD4*, as previously described. Various reports indicate that at least 60% to 70% and up to 95% of PAVMs are associated with HHT.[4–6] Additional associations reported in the literature include schistosomiasis,[42] mitral stenosis,[43] trauma,[43] actinomycosis,[43] Fanconi syndrome,[44] metastatic thyroid cancer,[45] and surgical correction of congenital heart disease.[46,47] However, many of these associations may be spurious rather than causative, as many represent single case reports.

Idiopathic PAVMs, not associated with HHT, are more commonly solitary and more evenly distributed throughout the lung. Because they are often solitary, idiopathic PAVMs are associated with fewer complications and are more easily treated with embolotherapy.[48]

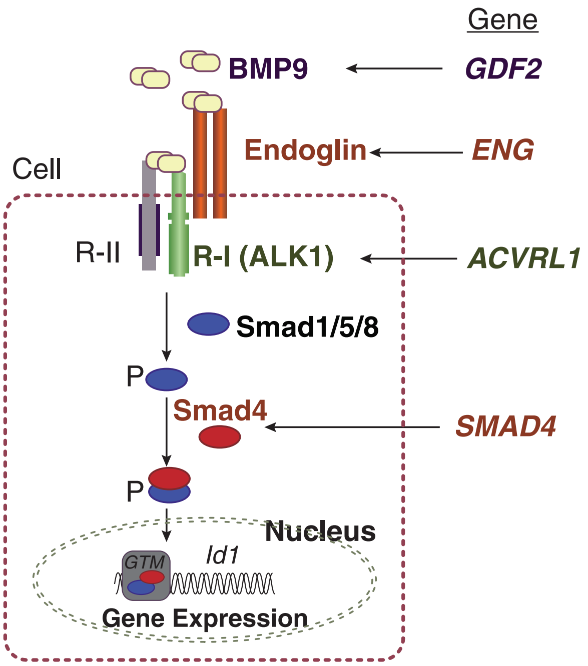

Figure 75-2 TGF-β cell signaling pathway, including the gene products of *ENG*, *ACVRL1*, and *SMAD4*, mutations in which are associated with HHT. *(Reproduced with permission from Wooderchak-Donahue WL, McDonald J, O'Fallon B, et al. BMP9 mutations cause a vascular-anomaly syndrome with phenotypic overlap with hereditary hemorrhagic telangiectasia. Am J Hum Genet. 2013;93(3):530–537.)*

Hepatic cirrhosis can cause a condition called hepatopulmonary syndrome (HPS), a pathologic dilatation of small vessels in the pulmonary circulation that leads to hypoxemia.[49] The pathology of HPS is distinctly different from that of PAVMs. HPS is caused by the release of vasoactive mediators including tumor necrosis factor α (TNF-α) and nitric oxide associated with portal hypertension and increased rate of enteric translocation of bacteria.[50] In contrast to PAVMs, HPS does not typically cause direct arteriovenous connection.

CLINICAL MANIFESTATIONS

Pulmonary AVMs are commonly asymptomatic, identified in many cases as an incidental finding on chest imaging or through screening of patients diagnosed with HHT. In general, symptoms of PAVM include dyspnea, exercise intolerance, and hemoptysis. Dyspnea on exertion is the most common respiratory symptom of PAVM but is not universally present, occurring in 14% to 59% of patients.[6,51–53] Hemoptysis is less common, occurring in 9% to 30% of cases[51,52] and ranging in severity from minor self-limited bleeding to massive hemoptysis. The severity of symptoms also depends on the disease burden of PAVMs in terms of number, size, and shunt fraction. Patients with diffuse microvascular PAVM are nearly universally symptomatic.[54] Given the significant overlap with HHT, many patients who have PAVM associated with HHT have nonpulmonary symptoms and features related to HHT rather than symptoms due to PAVM itself—for example, epistaxis is reported in up to 79% of patients with PAVM.[55]

There are several findings on physical examination that are associated with PAVM, although many cases lack physical findings. Hypoxemia, an effect of right-to-left intrapulmonary shunting in PAVM, is more common in severe cases with higher shunt fraction. A case series of patients with idiopathic PAVM (excluding patients with HHT diagnosis) found that 20% of patients had hypoxemia on presentation.[48] A much larger proportion of patients with diffuse PAVM are hypoxemic, 100% in one case series.[21] When severe, hypoxemia may be associated with cyanosis on exam.

In addition to hypoxemia, some patients may have positional variation in dyspnea and hypoxemia, referred to as platypnea and orthodeoxia, respectively. Platypnea is described as shortness of breath in the upright position that improves with reclining into a recumbent position[56] and is a rare finding in PAVM[57] despite being classically described. Orthodeoxia, defined as oxygen desaturation (by ≥2%) of arterial blood in the upright position and improved in the recumbent position, is more common, reported in 29%[57] to 65%[58] of patients with PAVM. These findings occur due to the predominance of PAVM in the lower lobes of the lungs, which leads to increased fraction of pulmonary blood flow through PAVMs (as a portion of the total pulmonary blood flow) in the upright position due to gravity's effect on the distribution of lung perfusion.[59] Although these findings are described in PAVM, they are not specific to this condition and are found also in other causes of right-to-left shunt such as hepatopulmonary syndrome[60] and intracardiac shunt (for example, via atrial septal defect or patent foramen ovale).[61]

Pulmonary bruit, a murmur-like sound auscultated over a PAVM, has been reported in pooled case series as occurring in 43% of patients.[19,62] This sound is attributed to the increased turbulent flow through a dilated AVM and is most commonly heard in the lower lobes during inspiration.

Cutaneous findings in patients with PAVM include telangiectasia and clubbing. Telangiectasias are small, dilated blood vessels found near the surface of the skin or mucous membranes. They manifest as small red partially-blanchable blemishes and most commonly present on the face, lips, tongue, oral mucosa, conjunctivae, and fingertips/nailbeds.[5]

Telangiectasias occur in about half of patients with PAVM[19] and are found almost exclusively in patients whose PAVMs are due to underlying HHT. Although reported frequently in older case series (in up to 82% of cases),[19] digital clubbing in more recent case series is found much less commonly, ranging from 0%[48] to 19%.[62] Clubbing is more common in cases with severe hypoxemia and cyanosis and has been noted to improve following embolotherapy for PAVM.

The most common laboratory abnormality attributable to PAVM is polycythemia, reported in 75% of patients with diffuse PAVM.[21] This finding, also known as secondary erythrocytosis, occurs as a compensatory mechanism for chronic hypoxemia through increased erythropoiesis in patients with adequate iron stores and serves to maintain adequate arterial oxygen content despite decreased oxyhemoglobin saturation.[63] Many patients with HHT lack this finding due to iron-deficiency anemia associated with chronic blood loss via gastrointestinal AVMs.

In the absence of concomitant lung disease, pulmonary function testing in patients with PAVM typically reveals normal spirometry and lung volumes. PAVM has been shown to have no substantial impact on the mechanical properties of the lung, even in patients with numerous and bilateral vascular lesions.[64–66] In contrast, diffusing capacity may be reduced and the alveolar-arterial oxygen gradient increased, reflective of abnormal gas exchange.[64,66] Despite resting hypoxemia, patients with PAVM in the absence of concurrent lung disease demonstrate normal peak exercise capacity, as measured by maximum oxygen consumption ($\dot{V}O_{2max}$). This is facilitated by compensatory mechanisms to maintain normal oxygen delivery to tissues despite reduced oxyhemoglobin saturation: polycythemia (assuming adequate iron stores) and increased stroke.[65] Patients with PAVM display relative hyperventilation at rest and with exercise, the magnitude of which is directly related to the magnitude of right-to-left shunt.[64,65]

COMPLICATIONS ASSOCIATED WITH PULMONARY AVMs

There are several known complications associated with PAVMs. These are related to a few different mechanisms: the associated hypoxemia and systemic adaptations, the loss of filtration by the pulmonary capillary bed allowing for arterial embolic disease, and hemorrhage due to PAVM rupture. The primary organ systems affected by PAVM-related complications are the pulmonary and neurologic systems.

■ Pulmonary Complications

Well described as a clinical feature of PAVM, hypoxemia is typically asymptomatic and well tolerated in this population, likely due to compensatory mechanisms that increase oxygen delivery to peripheral tissues like increased blood hemoglobin concentration (polycythemia), increased cardiac output, and increased ventilation.[67] However, long-term effects of chronic hypoxemia and polycythemia are not well studied in this population.

Hemorrhagic complications of PAVM are feared due to their life-threatening nature but are relatively rare. Hemorrhage occurs due to rupture of a PAVM sac and can manifest as bleeding into the airways and subsequent hemoptysis or bleeding into the pleural space surrounding the lung with development of a hemothorax. The incidence of hemorrhage due to PAVM is increased in pregnancy when an increase in cardiac output, blood volume, and vascular distensibility as well as hormonal effects contribute to an increased risk of bleeding.[68] Ference et al. documented an 8% incidence of life-threatening pulmonary hemorrhage (defined as either massive hemoptysis or hemothorax requiring hospitalization) in HHT patients with PAVM, with 27% of these cases occurring in pregnant women.[69] Pulmonary hemorrhage can also occur years after embolotherapy for PAVM due to formation of bronchial artery collateral circulation. Occasionally, patients with HHT may have hemoptysis due to endobronchial telangiectasias with or without PAVM, an alternate mechanism of bleeding.

PAVMs in patients with HHT may be associated with pulmonary hypertension, and although this may not be a direct complication of PAVMs, development of PH in this population can lead to significant morbidity including right heart failure and death. Typically, PAVMs create a low-resistance circuit through the pulmonary vasculature, lowering the pulmonary vascular resistance. However, patients with HHT may also have high cardiac output due to liver AVMs or anemia (due to enteric AVMs and chronic blood loss) that leads to an increase in pulmonary artery pressures.[70] Rarely, patients with HHT and PAVMs associated with mutation in the *ACVRL1* gene may have pulmonary arterial hypertension (PAH), caused by small vessel vasculopathy typical of idiopathic and other forms of PAH.[70,71] These changes include intimal hyperplasia, medial thickening, in situ thrombosis, and plexiform lesions. Caution should be exercised if embolotherapy is considered as treatment for patients with PAVMs and pulmonary hypertension, as occlusion of low-resistance flow through PAVMs could lead to worsened pulmonary hypertension and right heart failure.

■ Neurologic Complications

Neurologic complications are the most common type of complication in PAVM, observed in about 30% of patients.[19] These include migraine headaches, ischemic strokes, transient ischemic attacks (TIAs), and brain abscesses. Most of these complications occur because PAVMs allow small emboli (either septic or thrombotic) to bypass the pulmonary capillary bed that typically acts as a filter between the systemic venous and arterial systems.

Migraine headache is the most common neurologic complication of PAVM, occurring in 21% to 43% of patients,[58,72,73] although some series report a frequency as low as 4%.[74] Proposed mechanisms include migraine triggering by paradoxical emboli and modified metabolism of vasoactive amines.[67]

Ischemic strokes occurred in approximately 18% of PAVM patients in large case series, with TIAs occurring in 12% to 37% of cases.[58,62] In one retrospective study, 51% of patients admitted for PAVM occlusion were found on cerebral imaging to have evidence of either cortical or subcortical infarct; the frequency was highest in patients with multiple PAVMs.[75] Higher-grade right-to-left shunt on contrast echocardiography and feeding artery greater than 3 mm are associated with higher incidence of ischemic stroke,[76,77] suggesting that paradoxical embolism is the principal mechanism. Alternatively, there are reports of stroke due to impaired cerebral perfusion in the setting of polycythemia associated with PAVM.[77] Other risk factors for ischemic stroke in this population include low serum iron and fibrinogen[79] as well as low pulmonary artery pressure,[80] likely due to increased platelet aggregation and facilitated paradoxical embolism, respectively.

Brain abscess is another serious neurologic complication of PAVM, occurring due to the loss of pulmonary capillary filtration, which allows passage of septic emboli into the systemic arterial circulation and into the brain. This can occur even with transient bacteremia, such as with dental procedures. Brain abscess in PAVM occurs less frequently than ischemic stroke, with a prevalence ranging from 5% to 13% in various studies,[62,75,80] but it is associated with a high mortality rate of up to 24%.[21] Due to the increased risk of brain abscess compared with the general population, patients with known PAVM should receive prophylactic antibiotics prior to dental procedures and other nonsterile procedures with potential for bacteremia.[19]

DIAGNOSIS OF PULMONARY AVMs

Diagnostic evaluation for PAVMs should be pursued in patients in whom PAVMs are suspected due to clinical and/or radiographic features and in those with a known or suspected diagnosis of HHT. Patients with documented HHT whose initial screening for PAVMs is negative should undergo repeat screening after puberty, after pregnancy, within 5 years preceding planned pregnancy, and otherwise every 5 to 10 years.[81] Screening techniques assess for the presence of right-to-left shunting, most commonly with contrast echocardiography. Patients who have a positive screening test or who have a high pretest probability for PAVM should undergo diagnostic imaging to confirm the presence of PAVM, most commonly with chest CT.

■ Contrast Echocardiography

Contrast echocardiography (commonly referred to as a “bubble study”) is a standard screening tool for identification of PAVMs. In this test, echocardiography is performed in the apical four-chamber view while agitated saline (saline blended with a small amount of air) is administered intravenously. A right-to-left shunt is identified by the presence of microbubbles in the left atrium; delayed appearance of the microbubbles after four cardiac cycles is considered positive for an intrapulmonary right-to-left shunt (Fig. 75-3) as opposed to the immediate appearance in association with intracardiac shunts. A study of 281 patients with HHT who underwent screening contrast echocardiography for PAVMs demonstrated sensitivity and negative predictive value of 97% and 99%, respectively, using CT scans as the gold standard.[82] These excellent performance characteristics define contrast echocardiography as a highly suitable initial screening study, given that it is unlikely to miss clinically significant PAVMs.

Notably, contrast echocardiography is associated with a high false-positive rate, resulting in a positive predictive value as low as 51%.[82] This finding is primarily due to the identification of clinically insignificant “micro” PAVMs that are not detected on CT or post–treatment completion angiography[83] and would not be considered targets for treatment. This issue can be addressed by adding a grading system to contrast echocardiography, in which studies are graded by intensity of left heart opacification with microbubbles[84] (Fig. 75-4). Using a grading system to assess the severity of right-to-left shunt, patients with grade 1 shunt (<20 microbubbles) are unlikely to have visible PAVMs on follow-up CT[85] (Fig. 75-4). There are also other conditions that cause intrapulmonary right-to-left shunt (for example, hepatopulmonary syndrome) that should be considered in the absence of visible PAVM on CT scanning or other imaging modality.[86]

■ Other Assessments of Right-to-Left Shunt in Suspected PAVM

Assessment for right-to-left shunt in the initial stages of PAVM diagnosis can be performed though alternate methods other than contrast echocardiography. Degree of shunting can be calculated using the 100% inhaled oxygen method to determine the fraction of cardiac output that is shunted from right to left without oxygenation in the alveoli. In this method, an arterial blood gas is obtained after the patient breathes 100% oxygen via a tight-fitting mask or mouthpiece for 15 to 20 min; Pa_{O_2}, Sa_{O_2}, and Pa_{CO_2} are then used to calculate the shunt fraction. Various studies have shown that a measured shunt fraction greater than 5% has sensitivity of 98% for detection of clinically significant PAVMs.[19,87,88]

Radionuclide scanning can also demonstrate right-to-left shunt and can be useful as a screening tool for PAVM. In this test, ^{99m}Tc pertechnetate-labelled macroaggregated albumin or albumin microspheres are injected intravenously. The size of these

particles (ranging from 7 to 60 μm) is large enough to be filtered by the capillaries of the lung; however, anatomic right-to-left shunts such as in PAVM allow passage of these tagged particles into the arterial circulation and deposition into other tissues such as brain and kidneys. The shunt fraction can be calculated by quantifying the amount of deposition of radionuclide tracer in the systemic tissues as opposed to deposition in the pulmonary microvasculature. A small study of 19 patients with PAVMs demonstrated excellent agreement between shunt fractions determined by the radionuclide scan method and the 100% inhaled oxygen method.[89] Another study comprising 66 patients with HHT and PAVM showed that a shunt fraction greater than 3.5% on radionuclide scan performed after embolization had an 87% sensitivity and 61% specificity for detection of residual PAVMs.[90] Use of this imaging modality is limited, however, by cost and availability. It should be noted that radionuclide scanning and the 100% inhaled oxygen method identify the presence of right-to-left shunt rather than the anatomic location of the shunt (intrapulmonary vs. intracardiac). Use of contrast echocardiography provides more information about the location of the shunt based on the timing of bubbles seen in the left heart.

Other methods of PAVM screening have been investigated. One such method is transcranial Doppler (TCD) with agitated saline,[91] which has high sensitivity for right-to-left shunt (100%) but relatively low specificity (given the inability to distinguish between intrapulmonary and intracardiac shunting). However, the high negative predictive value (100% when using a cutoff of TCD grade <3) makes this a useful test for ruling out right-to-left shunt in at-risk patients in facilities where this test can be performed.

Chest Radiography

Although chest radiographs can reveal large PAVMs and have historically been included as part of the diagnostic evaluation, they will miss up to 60% of PAVMs.[88,92] As such, a normal chest radiograph does not rule out the presence of PAVM. However, presence of classic features of PAVM on chest radiograph is highly suggestive and specific. These features include a round, oval, or lobulated soft tissue mass, often situated in the lower lobes, with one or two adjacent pulmonary vessels that may extend to the mass from the hilum[19,93] (Fig. 75-5).

Computed Tomography

Computed tomography (CT) scanning is generally considered the gold standard for identification of PAVM because of its high sensitivity (98% in one study[17]) and ability to demonstrate the angioarchitecture, size, and location of individual PAVMs. It is commonly performed as a confirmatory test after contrast echocardiography demonstrates evidence of right-to-left shunting or in patients with a high clinical suspicion for PAVM. Helical CT scanning with thin (1- to 2-mm collimation) axial images and three-dimensional reconstruction provides the most detail for these lesions and can distinguish between vascular and nonvascular structures.[17,93,94] PAVM on CT classically appears as a well-defined peripheral lung nodule (with aneurysmal sac commonly 0.5–5 cm in diameter) that is rounded or multilobulated and has at least one feeding artery and one or more draining veins

(Fig. 75-6). Intravenous iodinated contrast administration can provide additional image detail with improved identification of feeding and draining vessels,[93] although contrast is not needed in most cases given the high spatial resolution and high contrast difference between bright pulmonary vessels and low-attenuating pulmonary parenchyma.

Magnetic Resonance Imaging

Magnetic resonance (MR) angiography is less commonly used for evaluation of PAVM, primarily due to its lower sensitivity compared with CT imaging. Initially studied using conventional spin-echo MR,[95] flowing blood within vessels results in absent or minimal MR signal intensity, giving this technique limited ability to distinguish small vessels from surrounding air-filled lung tissue.[19] More recent studies using breath-hold gadolinium-contrast-enhanced MR angiography,[96] ultrafast time-resolved 3D MR angiography,[97] and non-contrast-enhanced MR angiography with time-spatial labeling inversion pulse (time-SLIP MRA)[98] demonstrate improvements in sensitivity and imaging quality for detection of PAVMs, particularly

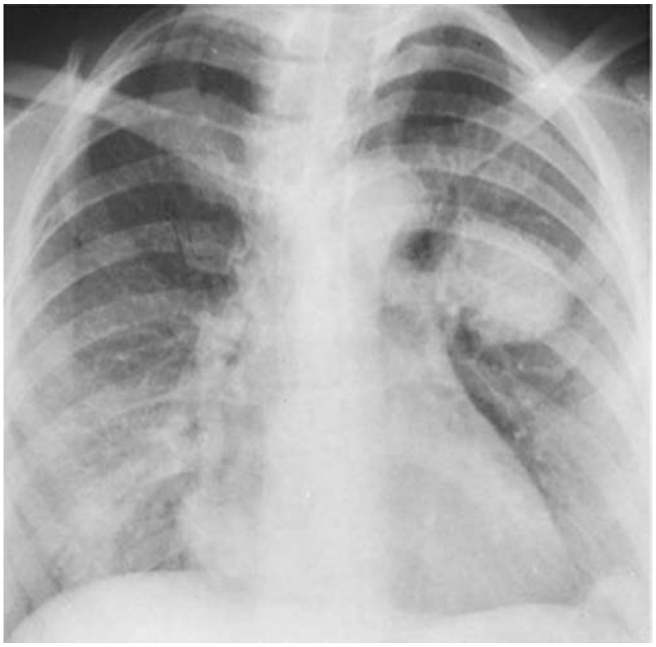

Figure 75-5 Pulmonary arteriovenous fistulas in a pregnant 24-year-old woman with hereditary hemorrhagic telangiectasia. Pre-existing pulmonary AVMs were found to be strikingly enlarged on chest radiograph at her seventh month of pregnancy. *(Reproduced with permission from Dr. M Rossman.)*

for clinically significant PAVMs with feeding artery diameter equal to or greater than 3 mm. However, use of MR angiography for diagnosis of PAVM remains limited due to longer breath-holding requirements, increased cost, and lower sensitivity and specificity compared to CT.

Pulmonary Angiography

Catheter pulmonary angiography is performed primarily for diagnostic confirmation at time of embolotherapy rather than as a standalone diagnostic test, as most PAVMs can be identified on noninvasive imaging. This technique involves introduction of an intravascular catheter into the pulmonary arterial circulation, followed by injection of radiopaque contrast through this catheter, and use of fluoroscopy to obtain dynamic images of the vessels filled with contrast including any PAVMs in the selected vascular bed. Pulmonary angiography provides detailed information about the angioarchitecture of individual PAVMs prior to embolotherapy, particularly when performed as hyperselective angiography in which the catheter is advanced to a distal pulmonary artery (at the segmental or subsegmental level) or to the feeding artery of an individual PAVM.[17] Digital subtraction angiography is commonly used to provide higher-quality images of blood vessels during angiography, with digital image processing to remove nonvascular structures from images obtained, allowing for lower radiation dose and contrast amount.

MANAGEMENT OF PULMONARY AVMs

Historically, thoracotomy with excision (ranging from wedge resection to total pneumonectomy) was the only treatment available for PAVM. This option carried risks associated with general anesthesia and thoracotomy and involved loss of lung tissue, particularly with repeat procedures. In the 1970s, endovascular mechanical occlusion was shown to be a successful option,[99] providing an alternative that soon supplanted surgery as the procedure of choice. PAVMs with feeding vessel diameter of 3 mm or larger should be embolized (even if symptoms are absent),[100] and PAVMs down to 2-mm vessel diameter are increasingly embolized if technically feasible. Patients with symptomatic PAVM should be considered for embolotherapy regardless of findings on noninvasive imaging. Diffuse PAVMs are less amenable to embolotherapy due to the presence of many small PAVMs that continue to contribute to symptoms and complication risk despite embolization of larger

visible PAVMs.[101] For patients whose PAVMs are smaller than the size threshold for interventional treatment and who are asymptomatic or minimally symptomatic, a strategy of observation and monitoring can be implemented instead. Management options are discussed in greater detail in the following section.

■ Endovascular Treatment

Embolization of PAVMs, also commonly referred to as embolotherapy, has become the standard first-line intervention for PAVMs that meet criteria for treatment. This minimally invasive procedure is performed endovascularly with placement of coils,[74] Amplatzer vascular plugs,[102] or microvascular plugs[103] to occlude blood flow through the embolized PAVM, reducing the shunt fraction and the risk for complications like brain abscess and embolic stroke[104] (Fig. 75-7). Detachable silicone or latex balloons also have been used but are now less commonly used due to limited availability. Embolization is considered successful if follow-up imaging shows more than 70% shrinkage of the draining vein or aneurysmal sac.[105] Embolotherapy may also be used in patients with diffuse PAVM to occlude blood flow to segments of lung with diffuse involvement, rather than targeting individual PAVMs.[22]

Risks of embolotherapy are low with essentially no reported mortality; adverse effects and complications include air embolism, pleuritic chest pain, hemoptysis, and migration or paradoxical embolism of embolization materials (potentially causing stroke or other end-organ injury). It has been shown that pulmonary artery pressure is not significantly increased by embolotherapy for PAVM in patients without baseline severe pulmonary hypertension,[106] although caution should be exercised in patients with pre-existing pulmonary hypertension, and severe pulmonary hypertension is considered a relative contraindication to PAVM embolization. Embolotherapy has been used successfully in pregnant patients as early as 16 weeks' gestation and has been found to be safe and effective.[68,107]

Coils for embolization are typically made of steel or platinum and are deployed into the feeding afferent vessel as close as possible to the aneurysmal sac. Obstruction of blood flow and prothrombotic coil materials/design (such as addition of nylon fibers) cause luminal thrombosis and PAVM occlusion.[108] However, shunt persistence after coil embolization has been observed in up to 25% of cases, with 91% of persistent PAVMs resulting from recanalization through an existing coil nest.[105] Recurrences can be effectively treated with repeat embolotherapy.

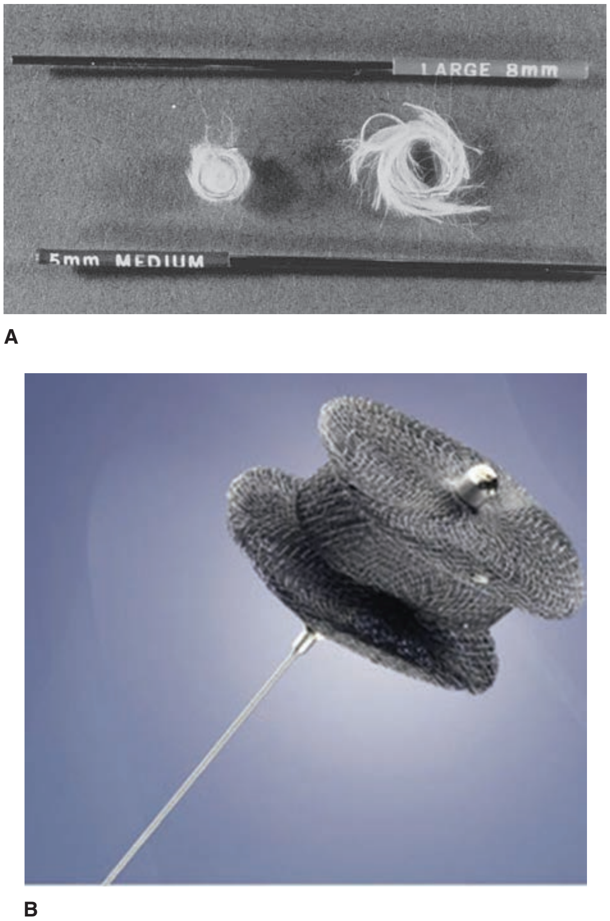

Figure 75-7 Embolotherapy devices. **A.** Embolization coils of two sizes. **B.** Amplatzer vascular occlusion plug.

Vascular occlusion devices such as Amplatzer vascular plugs and microvascular plugs are increasingly used as standard embolization devices for PAVM embolotherapy. These devices are typically composed of a self-expanding nitinol mesh and can be resheathed and redeployed if placement is not ideal after initial deployment.[102] Placement of a vascular plug into the feeding vessel of a PAVM can also be followed by coil embolization to the same vessel if perfusion of the PAVM is still seen on angiography[104] (Fig. 75-8). Successful initial occlusion of PAVMs with microvascular plugs and Amplatzer vascular plugs has been shown to occur in greater than 97% of cases,[103] and embolized PAVMs are less likely to recanalize with use of vascular occlusion devices compared to embolization with coils alone.[109]

A CT scan should be obtained within 6 to 12 months following embolotherapy and then repeated every 3 to 5 years in asymptomatic patients to evaluate for reperfused PAVMs or enlargement of previously small PAVMs now large enough for treatment.[81,110] Development of symptoms and signs of new or recurrent PAVMs should prompt more immediate imaging. Most patients have right-to-left shunting present on post-embolotherapy contrast echocardiography,[83] which limits its usefulness. A recent small study suggested that graded contrast echocardiography might have greater

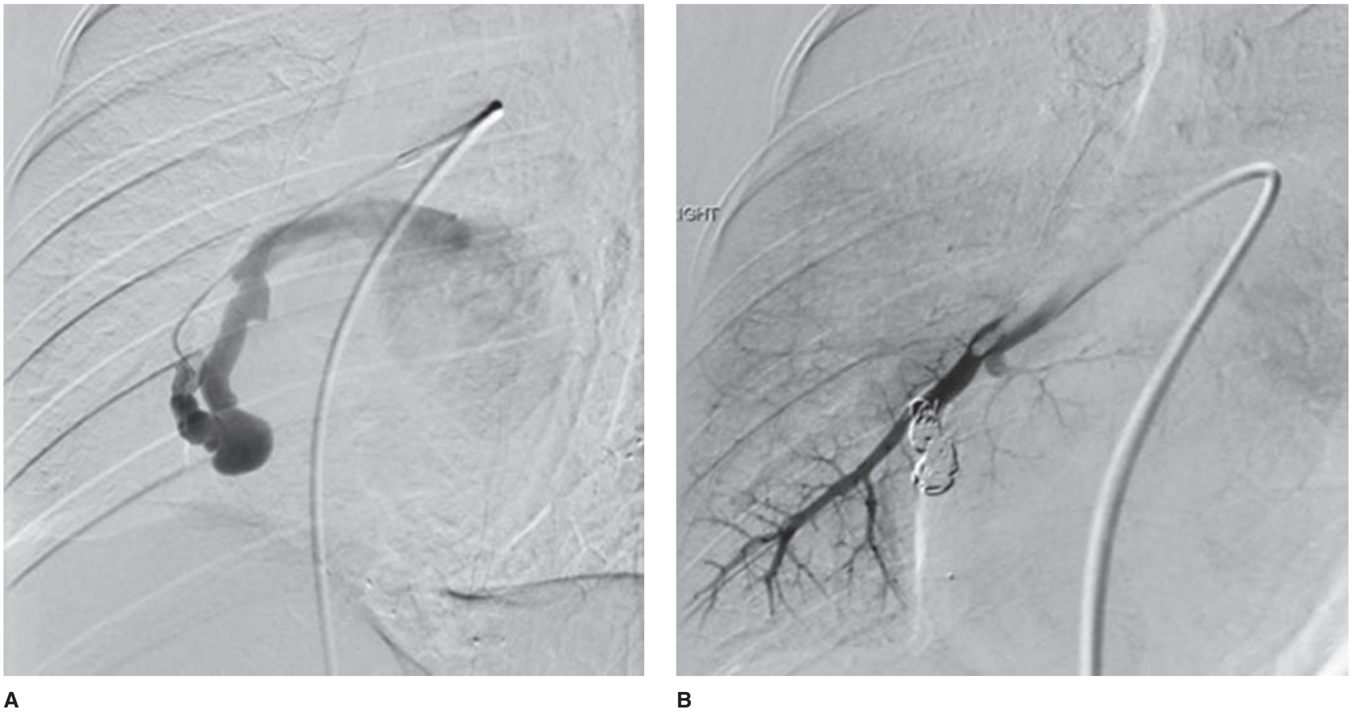

Figure 75-8 Successful embolization of a pulmonary arteriovenous malformation of the right middle lobe using a combination of a vascular plug and coil for complete embolization. **A.** Pulmonary angiography prior to embolotherapy demonstrates a simple PAVM with a single feeding artery. **B.** Pulmonary angiography following embolization shows absence of perfusion of the previously identified PAVM.

utility in predicting the need for repeat embolotherapy; no patients with grade 1 shunts had PAVMs amenable to embolotherapy by CT scan criteria. MR angiography has also been shown to be a feasible method of follow-up and may have a growing role in this area to minimize risk of radiation exposure.[111]

■ Surgical Treatment

With the advent of embolotherapy, surgical resection is now restricted to cases of PAVMs that are not amenable to embolization or select cases involving acute hemorrhage. Surgical excision can be customized in terms of extent based on necessity, ranging from local excision up to total pneumonectomy, with the goal of minimizing the loss of viable lung tissue. Lung transplantation is an option for patients with severe or diffuse disease not adequately treated with other options.[112,113] However this treatment option should be considered carefully given the significant risk of morbidity and mortality with lung transplantation and the demonstrated longevity of patients with PAVMs even with severe hypoxemia.[114]

■ Conservative Management

Asymptomatic patients with small (<2 mm feeding artery diameter) should be followed for development of symptoms, and CT imaging is recommended every 3 to 5 years given the risk of PAVM growth. Recent data demonstrating little to no growth of small and microscopic PAVMs during this time interval[115,116] have raised the possibility of safe extension of this interval to 5 to 10 years.

Certain adjunctive recommendations have been made to reduce the risk of paradoxical embolization of particles, air emboli, and septic emboli in patients with treated and untreated PAVM. Use of an inline filter during IV infusion is recommended to avoid introducing air or particles into the circulation. The size of inline filters is typically 0.22 to 0.45 μm, although blood filters ranging up to 260 μm are considered effective in avoiding large air emboli. Scuba diving should be avoided due to the increased risk of decompression sickness and paradoxical air embolism. Antibiotic prophylaxis should be used with dental procedures to reduce the risk of bacteremia and brain abscess,[117] and care should be taken to optimize dental hygiene.

Hypoxemia can be surprisingly well tolerated in patients with PAVM, primarily due to compensatory mechanisms like polycythemia, increased cardiac output, and improved aerobic conditioning to avoid tissue hypoxia. Patients who are symptomatic may benefit from use of supplemental oxygen, although hypoxemia due to PAVM does not typically improve with use due to the physiology of right-to-left shunting. Because secondary erythrocytosis is considered an adaptive response, therapeutic phlebotomy should be used only in cases of hyperviscosity with evidence of end-organ injury. Treatment of iron deficiency, particularly in cases of ongoing blood loss due to epistaxis and GI bleeding in HHT, is helpful in maintaining adequate erythrocyte production, an important component of adaptive response in PAVM.[67]

Special caution should be taken in pregnancy, as there is an increased risk of maternal death (1%), life-threatening pulmonary hemorrhage (1.4%), and stroke or myocardial infarction due to paradoxical embolism.[118] Although a majority of pregnancies in this population are ultimately uneventful, pregnancy in patients with PAVM (or HHT) is considered high risk, and patients considering pregnancy should be counseled about this risk and the need for careful monitoring during pregnancy and delivery.

PROGNOSIS

Prior to the development of embolotherapy in the 1970s, published case series reported PAVM-related mortality in patients with untreated PAVM ranging from 7.7% to 55%.[4,55,92,119–121] Untreated PAVMs are complicated by stroke and brain abscess as previously described, and these are sources of significant morbidity and mortality. Implementation of embolotherapy and recommended follow-up surveillance for PAVM has led to a significant reduction in morbidity and mortality. However, the risk of death or complication is higher in the subgroup of patients with bilateral diffuse PAVM, reported as 35% over a 27-year follow-up period in one case series, with a third of deaths due to PAVM-associated complications.[22] Risk factors for PAVM persistence on follow-up imaging include complex angioarchitecture[105] and smoking.[122]

CHAPTER 76

Nonmalignant Pleural Effusions

Christopher M. Kapp
David Feller-Kopman

INTRODUCTION

Pleural effusion occurs in more than 1.5 million patients each year in the United States.[1] The prevalence of ultrasound-detected pleural effusion in critically ill patients has been reported to be as high as 62%;[2] mortality is increased for those with an effusion.[3] Among the causes of pleural effusions, heart failure, pleural infection, and malignancy are most common.[4] Nonmalignant pleural effusions (NMPEs) arise from a vast assortment of conditions (Fig. 76-1); some etiologies have been associated with worse survival than effusions due to malignancy.[5,6]

PLEURAL ANATOMY AND PHYSIOLOGY

The pleural space is defined as the area between the visceral pleura, which lines the lung, including the fissures, and the parietal pleura, which lines the chest wall, diaphragm, and mediastinum. The visceral and parietal pleural membranes consist of a single layer of mesothelial cells, a layer of connective tissue, a superficial elastic layer, a loose connective tissue layer, and a deep fibroelastic layer.[7]

The normal pleural cavity is estimated to contain 0.26 mL of fluid per kilogram of body weight, with most of the fluid both produced and absorbed on the parietal surface.[8,9] Fluid production and resorption are dependent on the balance of hydrostatic and oncotic pressure differences between the systemic and pulmonary circulations and the pleural space. The lymphatic vessels in the parietal pleura are capable of increasing resorption by a factor of 20 in response to an increase in pleural liquid formation before being overloaded. Therefore, both a significant increase in fluid formation and a reduction in fluid resorption are required to produce a clinically significant pleural effusion.[8]

Pleural effusions typically form by one or more of the following mechanisms: (1) injury to the pleura that changes membrane permeability and leads to exudative effusions, (2) increased intravascular hydrostatic forces and/or decreased oncotic forces that lead to transudative effusions, and (3) extravasation of fluid from lymphatic or vascular structures or from translocation of fluid across the diaphragm.

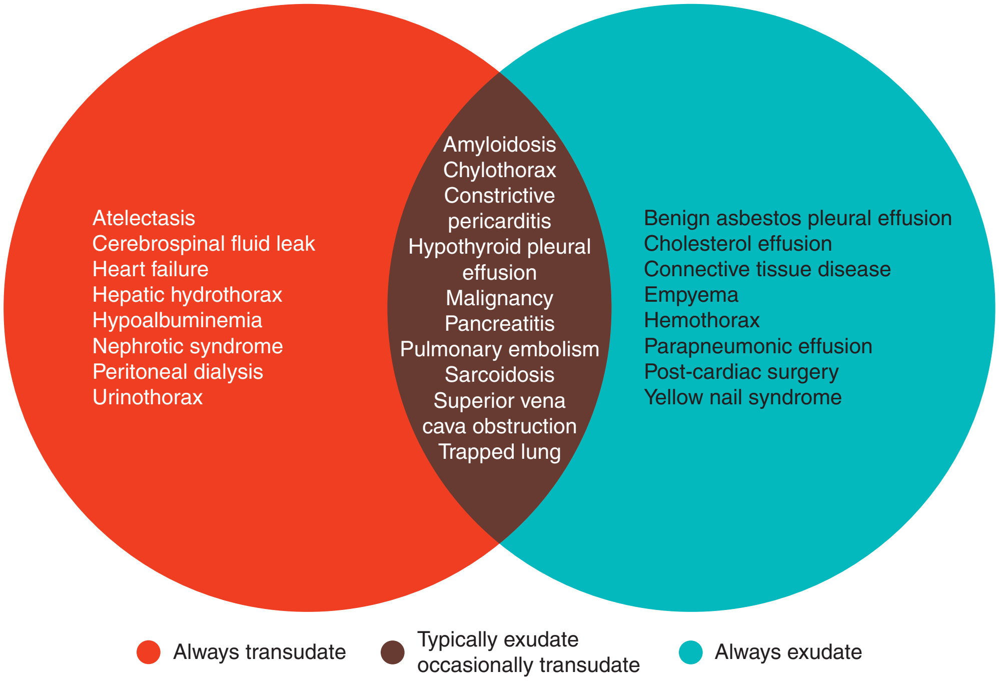
EPIDEMIOLOGY

There is a paucity of large-scale epidemiologic data describing the incidence or etiology of NMPEs. When speaking broadly about pleural effusions, the two most common causes are generally accepted to be related to congestive heart failure and parapneumonic effusion.[1] The third most common cause is believed to be a malignant pleural effusion, which is discussed elsewhere in this book. Rounding out the top five causes of pleural effusion are pulmonary embolism and viral illness.[10]

Table 76-1 depicts the most common causes of pleural effusions in the United States and their estimated annual incidence. Other causes of NMPE include chronic liver disease, renal disease, asbestos exposure, rheumatoid arthritis and other autoimmune diseases, and post-cardiac surgery.[10] As up to 30% of patients may have more than one cause of their pleural effusion (e.g., malignancy *and* congestive heart failure), a complete clinical evaluation may be necessary even in the setting of a seemingly obvious diagnosis.[11]

DIAGNOSTIC CONSIDERATIONS

Initial patient workup should begin with a thorough history and physical examination. When a pleural effusion is suspected, workup should be expeditious, as delay in diagnosis and treatment may lead to increased morbidity and mortality.[12]



Atelectasis
Cerebrospinal fluid leak
Heart failure
Hepatic hydrothorax
Hypoalbuminemia
Nephrotic syndrome
Peritoneal dialysis
Urinothorax
Amyloidosis
Chylothorax
Constrictive pericarditis
Hypothyroid pleural effusion
Malignancy
Pancreatitis
Pulmonary embolism
Sarcoidosis
Superior vena cava obstruction
Trapped lung
Benign asbestos pleural effusion
Cholesterol effusion
Connective tissue disease
Empyema
Hemothorax
Parapneumonic effusion
Post-cardiac surgery
Yellow nail syndrome
Always transudate
Typically exudate occasionally transudate
Always exudate

Figure 76-1 A non-exhaustive list of causes of pleural effusions and their characterization by Light's criteria.

TABLE 76-1 Most Frequent Causes of Pleural Effusions in the United States

Etiology	Annual Incidence (U.S.)
Congestive heart failure	500,000
Infectious etiology	300,000
Malignancy	200,000
Pulmonary embolism	150,000
Viral illness	100,000
Cirrhosis	50,000
Post–cardiac surgery	50,000

TABLE 76-2 Rules to Classify Pleural Fluid as Exudate Versus Transudate

Rule	Criteria
Light's criteria	PF/serum protein ratio >0.5, or PF/serum LDH ratio >0.6, or PF LDH > two-thirds upper limits of the laboratory's normal serum LDH
Rule that does not require serum tests	PF protein >2.9 g/dL, or PF cholesterol >45 mg/dL, or PF LDH >0.45 times upper limit of the laboratory's normal serum LDH

LDH, lactate dehydrogenase; PF, pleural fluid.

Often, a pleural effusion is discovered when an imaging study is performed for another reason (e.g., chest x-ray for cough). A patient's history is frequently nonspecific, as patients may describe pleuritic chest pain, dyspnea, and a dry, nonproductive cough. Special attention should be paid to past occupational exposures (e.g., asbestos), exposures to infectious diseases (e.g., tuberculosis), and underlying medical conditions (e.g., congestive heart failure, cirrhosis, collagen vascular disease, malignancy). Further, medication history may be important, as some commonly used drugs have been implicated as causes to pleural effusions, including methotrexate, amiodarone, and beta blockers.[13] The physical examination may provide clues to the presence of more common causes of pleural effusion, such as collagen vascular disease or heart failure, as well as more obscure causes, such as yellow nail syndrome. Once an appropriate differential diagnosis is devised, the clinician should choose wisely the next steps in diagnostic evaluation—which frequently include the assessment of other organ systems.

When selecting the best test to evaluate the pleuropulmonary space, current guidelines recommend the use of upright chest x-ray as an initial test.[14] It should be noted that supine and semirecumbent chest x-rays frequently underestimate the size of a pleural effusion, and that the lack of a meniscus sign on chest x-ray does not preclude existence of an effusion.[15] Once an effusion is confirmed or strongly clinically suspected on x-ray, a thoracic ultrasound should be performed, even before more advanced imaging, such as computed tomography. The use of portable, point-of-care ultrasound has significantly improved our ability to quantify, predict etiology, and access pleural effusions and is often the imaging modality of choice in the intensive care unit.[16–19] The reader is referred to Chapter 29 for further details on thoracic ultrasonography.

The sonographic characteristics of a pleural effusion may be useful in helping the clinician determine the nature of the fluid and deciding on whether to perform thoracentesis or tube thoracostomy.[20] A transudative effusion is typically be anechoic, while an exudative effusion may be anechoic, complex and septated, complex and nonseptated, or homogenously echogenic.[21] While evidence of septations may suggest an exudate and a complicated effusion, septations are not specific for infection.[18,21] Additional imaging findings that can be detected on ultrasound are the thickness of the pleura and pleural nodules.[18] Sonographic evidence of pleural thickening greater than 7 mm or presence of a pleural nodule are predictive of a malignant pleural effusion.[18,22]

■ Thoracentesis

Pleural effusions with greater than 1 to 2 cm of fluid separating the visceral and parietal pleura should undergo pleural drainage, assuming that there are no safety concerns (e.g., uncorrectable coagulopathy, patient agitation) that preclude safe performance of the procedure. One notable exception is a clinical setting suggestive of congestive heart failure; a trial of diuresis is the recommended first step, reserving thoracentesis for patients who fail to respond appropriately.[23] Thoracentesis is a well-tolerated procedure, even in patients requiring positive pressure ventilation, and the safety profile improves with use of thoracic ultrasound and in the hands of an experienced proceduralist.[14,24,25]

Transudates versus Exudates

Categorization of the fluid as a transudate or an exudate simplifies the differential diagnosis and may guide management of the effusion.[26] Light's criteria for differentiating exudate from transudate have remained the standard method of initial categorization of pleural effusions since their inception in 1972.[27] Light's criteria focus on the use of pleural fluid lactate dehydrogenase (LDH) and pleural fluid total protein relative to their serum values (Table 76-2)[27] for distinguishing between transudates and exudates. Light's criteria serve as a very sensitive test, correctly classifying nearly all exudates. Approximately 25% of transudates are misclassified as exudates, particularly in the setting of heart failure patients who are receiving diuretics.[28,29] Alternative rules, listed in Table 76-2, avoid some of these limitations and perform equally as well as Light's criteria.[30–32] There are a battery of both routine and specialized tests that can be sent for pleural fluid analysis, depending on the pretest probability of the diagnosis (Table 76-3).

■ Pleural Biopsy

Pleural biopsy can be considered for patients with an exudative effusion who remain undiagnosed after initial thoracentesis. The approach to pleural biopsy ranges from minimally invasive (i.e., a closed needle biopsy with an Abrams needle), to image-guided percutaneous pleural biopsy, to biopsy by video-assisted thoracoscopic surgery (VATS) or medical thoracoscopy (also referred to as pleuroscopy).[33,34]

Medical thoracoscopy, often performed under moderate sedation and local anesthesia, is an alternative to VATS, which is commonly performed under general anesthesia. The other main difference between VATS and medical thoracoscopy is that medical thoracoscopy is typically limited to biopsy of the parietal pleura and adjunctive procedures, such as pleurodesis or placement of an indwelling pleural catheter (IPC), whereas more complex surgeries can be performed with VATS. A review of 78 medical thoracoscopy and 99 VATS procedures showed no difference in diagnostic yield, major or minor complications, or need for additional pleural procedures. However, there was a significantly longer length of stay and higher cost associated with VATS.[35]

TABLE 76-3 Pleural Fluid Test Results and Commonly Associated Conditions

Test	Result	Most Common Suggested Conditions
Erythrocytes	PF/S HCT >0.5	Hemothorax
Neutrophils	>10,000/μL	Parapneumonic effusion, lupus pleuritis, acute pancreatitis
	>50,000/μL	Empyema
Lymphocytes	>85%–95%	TB pleurisy, sarcoid, chronic rheumatoid pleurisy, yellow nail syndrome, chylothorax
Eosinophils	>10%	Hemothorax, pneumothorax, benign asbestos pleurisy, pulmonary infarction, coccidioidomycosis, paragonimiasis and other parasites, drug-induced pleurisy, duropleural fistula, Churg–Strauss syndrome, sarcoidosis, TB pleurisy
Protein	<1 g/dL	Peritoneal dialysis, CVC erosion, duropleural fistula
	>4 g/dL	TB pleurisy
LDH	>1000 IU/L	Bacterial empyema, paragonimiasis, amebic empyema, septic emboli, rheumatoid pleurisy
Glucose	PF/S <0.5	Complicated parapneumonic effusion, chronic rheumatoid pleurisy, paragonimiasis, amebic empyema, esophageal rupture, TB pleurisy, lupus pleuritis, urinothorax
	PF/S >1	Peritoneal dialysis, CVC erosion
pH	<7.30	Esophageal rupture, chronic rheumatoid pleurisy, complicated parapneumonic effusion, paragonimiasis, amebic empyema, TB pleurisy, lupus pleuritis, urinothorax, pancreaticopleural fistula
Amylase	Elevated	Esophageal rupture, acute pancreatitis, pancreaticopleural fistula
Cholesterol	>200 mg/dL	Cholesterol effusion
Creatinine	PF/S >1	Urinothorax
Beta 2 transferrin	Elevated	Duropleural fistula, ventriculoperitoneal shunt migration
Triglycerides	>110 mg/dL	Chylothorax, CVC erosion if lipids infused
Chylomicrons	Present	Chylothorax
Bilirubin	PF/S >1	Biliopleural fistula
Glycine	PF/S >1	Glycinothorax
ADA with lymphocytosis	>40 IU/dL	TB pleurisy

ADA, adenosine deaminase; CVC, central venous catheter; TB, tuberculous.

As medical thoracoscopy provides the ability to perform visualized biopsies of the pleura, this procedure has generally replaced biopsy using an Abrams needle. The one notable exception is in areas of the world that have a high prevalence of tuberculosis, since Abrams needle biopsy has a relatively high diagnostic yield in diagnosing tuberculous effusions.

TRANSUDATIVE EFFUSIONS

Selected etiologies of transudative pleural effusions are discussed in the following sections. They include common causes (e.g., congestive heart failure, liver cirrhosis, nephrotic syndrome) and rare causes (e.g., constrictive pericarditis, urinothorax, Meigs syndrome, peritoneal dialysis, cerebrospinal fluid leakage, ventriculoperitoneal shunts).

■ Congestive Heart Failure

Consistent with cardiac disease being the leading cause of death in the United States, it is also the most common cause of pleural effusion, with a prevalence of 50% to 90% in persons hospitalized with congestive heart failure (CHF).[36,37]

The mechanism of pleural fluid collection in CHF is related to an elevated left atrial pressure that generates pulmonary edema and provokes leakage of interstitial lung water down a hydrostatic pressure gradient into the pleural space.[38,39] Elevated left ventricular pressures have been implicated as an essential factor for producing CHF-related effusions; however, transudative effusions may also occur in a minority of patients with pulmonary arterial hypertension and isolated right ventricular failure.[40] Pleural effusions related to CHF are classically bilateral (60%–85%) and larger on the right side. When unilateral, they occur more commonly on the right, with a ratio of 2:1 right-sided to left-sided.[23]

Initial management of a suspected CHF pleural effusion involves a trial of diuresis. A thoracentesis may be considered if effusions fail to improve or resolve with diuretics. NT-proBNP is a sensitive marker of a CHF exacerbation, and elevated levels may be helpful in discriminating transudates associated with CHF from other etiologies.[41] Pleural fluid NT-proBNP correlates linearly with serum levels and can be used to help identify CHF-related effusions.[42] In cases where the serum NT-proBNP is very elevated and CHF is the lone suspected cause of the effusion, pleural drainage is not indicated except for providing symptomatic relief after failed diuresis.

Classically, CHF-related effusions are transudative; however, up to 30% of effusions fulfill Light's criteria for an exudate.[28,29] Pathophysiologic mechanisms for exudative pleural effusions in CHF include (1) fluid formation as a byproduct of a coexisting diagnosis (e.g., pulmonary embolism or recent cardiac surgery);[43] (2) water reabsorption that is more rapid than reabsorption of other molecules in the pleural space, resulting in a rise in the concentration of protein and LDH with diuresis;[23,28] and (3) elevated fluid erythrocyte counts (>10,000/μL), causing LDH release during autolysis of red blood cells.[44] Several strategies for determining that an exudative effusion in the setting of CHF is related to heart failure, rather than a comorbid condition, are listed in Table 76-4.

With improvement in heart function and volume status, CHF-related pleural effusions gradually resolve. Rarely, effusions in patients with refractory heart failure may require pleurodesis or placement of an IPC for palliation of symptoms, both of which may successfully palliate symptoms in up to 92% of patients.[45–48] IPCs may obviate the need for repeated thoracenteses and recurrent hospitalization and should be considered in select patients with the ability to manage them safely at home.[47]

TABLE 76-4 Rules for Evaluating Heart Failure–Related Effusions Misclassified as Exudates

Test Results	Comments
• PF-to-S albumin gradient >1.2 g/dL • PF/S albumin ratio <0.6 • PF-to-S protein gradient >3.1 g/dL (less accurate than the albumin-based tests above)	These three rules more accurately establish CHF as cause of an effusion for patients with a high pretest probability of CHF compared with Light's criteria
• Serum assay of amino terminal fragment of proBNP (NT-proBNP) >1500 pg/mL CHF-related <400 pg/mL CHF-unrelated	More accurate than protein or albumin-based testing rules
• Pleural fluid assay of NT-proBNP >1500 pg/mL CHF-related <400 pg/mL CHF-unrelated	High accuracy but no advantage over serum NT-proBNP
• Pleural fluid BNP >400 pg/mL CHF-related <100 pg/mL CHF-unrelated	Lower discriminative properties compared with NT-proBNP

BNP, brain natriuretic peptide; PF, pleural fluid; S, serum.

Hepatic Hydrothorax

Hepatic hydrothorax occurs when a pleural effusion develops in a patient with liver cirrhosis and portal hypertension in the absences of cardiopulmonary disease.[49] Hepatic hydrothorax is characterized by a transudative pleural effusion greater than 500 mL and is a relatively rare complication of cirrhosis, occurring in only 5% to 10% of cirrhotics.[50] The disorder has also been reported in 2% of liver transplant recipients with prior hepatitis C infection.[51]

The pathophysiology is believed to be related to the accumulation of ascites in the peritoneal cavity that herniates blebs of peritoneum into the chest through small diaphragmatic irregularities.[50] When these blebs rupture, ascites flows from the positive-pressure peritoneal space into the negative-pressure pleural space.[52] Small (<1 mm) diaphragmatic defects have also been visualized, and studies using air, blue dye, and iodine 131–labeled albumin have confirmed transdiaphragmatic migration through the defects.[53,54] These stomata occur more commonly in the tendinous portion of the right hemidiaphragm compared with the thicker, more muscular left, leading to 80% of hepatic hydrothoraxes occurring on the right side, 18% on the left, and 2% bilateral.[55] Up to 20% of patients will not have clinically apparent ascites due to decompression of the abdominal fluid into the pleural space,[56,57] but ultrasound or CT will demonstrate residual ascites in the large majority patients.[58]

Clinically, patients with hepatic hydrothorax may have a diverse presentation, ranging from asymptomatic to varying degrees of dyspnea, depending on effusion size and underlying cardiopulmonary disease. In rare instances, respiratory failure may occur in persons with rapid development of pleural effusion secondary to ascites and sudden rupture into the pleural space.[57] Thoracentesis yields a transudative effusion in 94% of patients.[56] Light's criteria may misclassify up to 18% of hepatic hydrothoraces as exudates; some authors suggest that a pleural fluid–to–serum albumin ratio of <0.6 is more accurate in this group of patients.[59] Diagnosis is one of exclusion, and caution must be exercised in assuming that an effusion in a cirrhotic patient is due to hepatic hydrothorax. A prospective study of 60 cirrhotic patients with pleural effusions showed that 30% were from conditions other than hepatic hydrothorax (e.g., pleural tuberculosis, malignancy, spontaneous bacterial empyema), particularly in patients with left-sided effusions.[53]

Management of hepatic hydrothorax closely resembles that of abdominal ascites, including dietary sodium restriction, diuretic therapy, and symptom management with thoracentesis. A transjugular intrahepatic portosystemic shunt (TIPS) can also be considered and has been demonstrated to achieve a good clinical response in refractory cases.[60] Hepatic hydrothorax typically resolves after liver transplantation. Outcomes in transplanted patients with hepatic hydrothorax are not inferior to those without.[61]

Chest tube placement, with or without pleurodesis, is often ineffective in treatment of hepatic hydrothorax, as more than one-quarter of patients fail due to rapid reaccumulation of fluid.[62]

Complications of pleurodesis include pain, fever, pneumothorax (due to non-expandable lung), and renal failure (likely secondary to intravascular volume depletion similar to patients undergoing large-volume paracentesis).[62]

IPCs have been used in refractory cases of hepatic hydrothorax, sometimes as a bridge to transplantation. While IPCs provide successful palliation of dyspnea, complications appear to be higher than in those with malignant pleural effusion, with empyema the most common.[63,64] If an IPC is considered, a multidisciplinary discussion involving members of the hepatology and transplant surgery teams should be conducted prior to placement.

Constrictive Pericarditis

Greater than 50% of patients with constrictive pericarditis develop a pleural effusion, which can be the initial presentation of pericardial disease.[65] The pathogenesis is not well understood but may be related to migration of coexisting ascites into the pleural space or compromised left ventricular function that causes a transudative effusion.[66] Constrictive pericarditis may occur as a result of surgery, radiation, or infectious etiologies; obtaining a diagnosis may be helpful in treatment. The effusions may resolve once the pericarditis is treated. In cases without an obvious medical cause, pericardiectomy can be considered, although this procedure is associated with significant morbidity.

Nephrotic Syndrome

Pleural effusions may be seen in up to 21% of patients with nephrotic syndrome.[67] They are typically related to severe hypoalbuminemia and are usually seen only when the serum albumin is <2 g/dL. Increased hydrostatic pressure due to salt retention and hypervolemia are contributing factors in their development. The effusions are typically bilateral; treatment focuses on decreasing protein loss in the urine, use of diuretics, and a low-sodium diet.

Urinothorax

Urinothorax is defined by the presence of urine in the pleural cavity and typically occurs secondary to obstructive uropathy. It is a rare cause of pleural effusion, which is predominantly unilateral and typically very large, occupying more than two-thirds of the hemithorax.[68,69] If suspected, the diagnosis is supported by pleural fluid that has the odor of urine and is characterized by low protein concentration but high LDH. The diagnosis is confirmed by demonstrating a pleural fluid–to–serum creatinine ratio of >1, along with imaging confirming obstructive uropathy. Relief of the obstruction successfully treats the urinothorax in the vast majority of cases.[69]

Peritoneal Dialysis

Pleural effusion is a rare complication of peritoneal dialysis (PD), affecting approximately 2% of all PD patients.[70,71] The pathophysiology is linked to passage of dialysis fluid from the positive-pressure peritoneal cavity into the negative-pressure pleural cavity via pleuroperitoneal communications resulting from diaphragmatic blebs or defects, similar to patients with hepatic hydrothorax.[70] The effusion is typically unilateral and transudative. The diagnosis rests on demonstration of an elevated pleural fluid glucose concentration exceeding that of plasma. Management centers around interruption of PD, and if an alternative method of dialysis is not a permanent option, thoracoscopic pleurodesis or repair of the diaphragmatic defects can be performed before reinitiation of PD.[70]

■ Cerebrospinal Fluid Leakage into the Pleural Space

Cerebrospinal fluid (CSF) may be the etiology of a pleural effusion when a duropleural fistula forms. Occurrence is rare, and typically results from trauma, as a complication from spinal or thoracic surgery, or due to rupture of a pre-existing intrathoracic meningocele.[72,73] The presence of headache, nausea, vomiting, meningismus, and other neurologic findings serve as clues that a duropleural fistula might be the underlying cause of pleural effusion.[74]

The pleural fluid is typically clear, is essentially acellular, and has low protein and LDH concentrtations.[73] Beta-trace protein and beta-2 transferrin are specific biomarkers that can be measured in the pleural fluid in cases where a duropleural fistula is suspected.[75] Once confirmed, these effusions rarely subside on their own and typically require surgical intervention.

■ Ventriculoperitoneal Shunts

Pleural effusion is a rare complication of an indwelling ventriculoperitoneal (VP) shunt, typically placed for hydrocephalus not responsive to medical management.[76] This can be due to catheter tip migration into the thorax or to efflux of fluid from the peritoneal cavity through diaphragmatic defects.[76,77] Pleural fluid characteristics are consistent with typical CSF, with no cells, low protein and LDH, and elevated beta-2 transferrin.[72] A radionuclide shunt-gram may confirm the diagnosis.[77,78] Treatment involves revision of the shunt.

■ Trapped Lung

Non-expandable lung serves as an "umbrella" term for trapped lung and lung entrapment.[79,80] Lung entrapment effusions are typically exudative and related to an acute or subacute underlying condition (e.g., malignancy, infection).[80,81] With pleural drainage, the lung fails to expand due to the development of visceral pleural thickening, endobronchial obstruction, or any disease process that increases pulmonary elastic recoil (e.g., lymphangitic carcinomatosis). Entrapment may resolve if the underlying inflammatory process improves (e.g., underlying pneumonia), or it may progress to trapped lung.

Trapped lung results from abnormal healing of an exudative effusion (e.g., post-CABG), development of visceral pleural thickening, and formation of a "pleural effusion ex-vacuo." Once the initial inflammatory process has resolved, the corresponding pleural effusion associated with trapped lung is typically transudative.[80,82]

Many patients with trapped lung are asymptomatic, and the diagnosis is frequently not discovered until pleural fluid drainage is attempted.[83] With drainage of the effusion, patients may develop chest discomfort, likely related to the significant decrease in pleural pressure.[84] Pleural manometry can help distinguish lung entrapment from trapped lung; however, manometry has not been shown to prevent the development of chest discomfort during thoracentesis.[84,85] As patients are often asymptomatic, treatment for trapped lung is observation and reassurance. Those with significant dyspnea can be evaluated for placement of an IPC or VATS decortication.[86,87]

EXUDATIVE EFFUSIONS

Causes of nonmalignant, exudative effusions are common, including infection, pulmonary embolism, and cardiac surgery–related; less common etiologies include chylothorax and hemothorax. The following section discusses diagnosis and management of exudative pleural effusions.

■ Parapneumonic Effusions and Empyema

The clinical significance of an infected pleural space has been known for centuries. According to Hippocrates, "Persons who become affected with empyema after pleurisy, if they get clear of it in forty days from the breaking of it, escape the disease; but if not, it passes into phthisis."[88] Parapneumonic effusion (PPE) and empyema are the most common exudative effusions and stem from infection in the lung parenchyma.[89]

Parapneumonic effusions constitute any effusion due to an underlying pneumonia, whereas empyema is defined as the presence of purulent pleural fluid or a positive pleural fluid Gram stain or culture. A parapneumonic effusion results when inflammatory cells migrate to the pleural space from an adjacent zone of lung infection and release pro- and anti-inflammatory cytokines that alter pleural membrane permeability, leading to recruitment of additional inflammatory cells.[90–92] This leads to an influx of protein-rich fluid, initially creating a sterile and free-flowing effusion. Development of a parapneumonic effusion may be followed by invasion of bacteria into the space, leading to neutrophilic pleocytosis, increased LDH, increased platelet-activating factor, and decreased fibrinolytic activity that favors fibrin deposition in the pleural space.[93]

PPEs occur in 20% to 57% of patients hospitalized for community-acquired pneumonia; the incidence has been increasing, especially in the elderly population.[12,94,95] Patients with PPE have increased mortality compared with patients with pneumonia who do not have an effusion.[94,96,97] Delayed drainage is associated with a higher mortality.[98]

Risk factors for PPEs include diabetes, immunosuppression, alcoholism, cancer, poor dental hygiene, and increased severity of the pneumonia index.[99] Parapneumonic effusions are classified as uncomplicated when effectively treated by antibiotics alone, and complicated when pleural drainage is required.[100,101] Table 76-5 delineates commonly ordered tests in evaluation of suspected infectious effusions and provides parameter values that may suggest a diagnosis.

The clinical presentation of PPE and empyema are typically those of the underlying pneumonia—cough, fever, and sputum, as well as chest pain. It should be noted, however, that in elderly patients, these symptoms are frequently absent, and anemia, fatigue, and failure to thrive often predominate, making the clinical diagnosis more difficult.[99,102] Potentially related to underdiagnosis, elderly patients often present with a more complicated pleural space, leading to higher failure rates of nonsurgical therapy.[103] Table 76-6 highlights the natural timeline of an empyema.

Treatment of patients with PPE and empyema relies upon the selection of appropriate antibiotics. Patients with community-acquired pneumonia typically require coverage for *Streptococcus* species and anaerobes (e.g., *Bacteroides*), while patients with a hospital-acquired infection will, at least initially, require therapy directed at more resistant pathogens (e.g., methicillin-resistant *Staphylococcus* and *Enterobacter*).[104]

In addition to antibiotics, drainage of the pleural space is an essential component of treatment. Drainage should initially be attempted with a tube thoracostomy. Data derived from large retrospective studies suggest that outcomes related to mortality and need for subsequent surgery are equivalent with use of small-bore tubes (≤14-French) compared to larger-bore tubes. Additionally, smaller tubes are associated with less pain during insertion and while in

TABLE 76-5 Commonly Ordered Pleural Fluid Tests

Test	Clinical Significance
Cell count and differential	Leukocyte counts vary depending on the stage of empyema formation; frank empyemas may have low leukocyte counts because cells have undergone lysis. The effusions are neutrophil predominant although a mononuclear cell predominance may exist with partially treated parapneumonic effusions.
Protein	Defines an exudate when >3.0 g/dL. Tuberculous effusions almost invariably >4.0 g/dL. Values >7.0 g/dL suggest Waldenström macroglobulinemia, multiple myeloma, or a cholesterol effusion.
LDH	Defines an exudate in Light's criteria rule; usually >1000 IU/L in empyemas.
Microbiologic staining and culture	Microbiologic staining and culture with sensitivity blood culture bottles. Cultures positive in ~60% of patients who have signs of pleural infection.
pH and glucose	Pleural fluid pH and glucose decrease because of intrapleural bacterial metabolism and inflammatory cell activity that utilize glucose and release lactic acid. A PF pH <7.20 and glucose <60 mg/dL suggest that a parapneumonic effusion is complicated and requires drainage. The studies upon which these recommendations are based, however, have extensive limitations in design.
Amylase (ordered in selected settings)	Elevated in patients with empyema secondary to esophageal rupture (elevated salivary isoenzyme of amylase); elevated in pancreaticopleural fistula (elevated pancreatic isoenzyme of amylase).

LDH, lactate dehydrogenase; PF, pleural fluid.

TABLE 76-6 Stages of an Empyema

Exudative	Increased permeability of pleural membranes with influx of inflammatory cells and protein-rich exudate. Most patients will respond to antibiotics without pleural drainage.
Fibrinopurulent	
Early fibrinopurulent	Increased procoagulant activity in the pleural space promotes deposition of fibrin with early septation of the effusion. Pleural fluid becomes more viscous with increasing LDH and decreasing glucose and pH. Some patients may respond to antibiotics alone but drainage becoming increasingly likely.
Late fibrinopurulent	Extensive fibrin deposition on pleural membranes causing loculations and pleural rind. Viable bacteria present with markedly increase PF LDH and low glucose and pH. Pleural fluid appears macroscopically purulent. Pleural fluid drainage and possibly decortication required.
Organizing	Fibroblast proliferation generates a fibrous pleural peel that requires decortication. A trapped lung may occur if the empyema space is not obliterated.

place.[105] Tubes smaller than 12-French have a higher failure rate in empyema,[105] making a 14-French tube a reasonable initial choice in most situations.

If the pleural space is not fully drained with a chest tube alone, typically due to a multiloculated space, instillation of tissue plasminogen activator (t-PA) and DNAse has been demonstrated to achieve effective drainage, a lower likelihood of being referred for surgery, and a shorter mean hospital stay.[105] Despite improvements in these clinical outcomes, a mortality benefit has not yet been demonstrated with t-PA and DNAse. Additionally, t-PA is associated with a median hospital length of stay of 12 days, which is considerably longer than the 5- to 7-day length of stay reported in series employing VATS drainage.[106–109] Pleural thickening >4 mm, a parenchymal abscess, or necrotizing pneumonia were found to be predictors of treatment failure.[110]

Saline irrigation alone via tube thoracostomy for pleural infection has been shown in a pilot study to improve pleural fluid drainage and decrease surgical referral[111] and, thus, can be used in patients who are not candidates for surgery or tPA/DNAse.[112]

Indications for, and optimal timing of, surgical drainage in PPE and empyema are less clear. VATS may be definitive treatment in 85% to 91% of patients and, as noted above, may actually shorten length of stay compared to nonsurgical management.[106,113] Earlier surgery has been associated with a lower risk of conversion to thoracotomy and fewer complications than when performed later in the disease course.[114] Based upon the assumption that earlier surgical intervention may be warranted in patients at higher risk for poor outcomes, a risk stratification model has been developed that predicts mortality at 3 months. The RAPID (Renal function, Age, Purulence, Infection source, Dietary factors) scoring system classifies patients at presentation into low-, medium-, and high-risk categories that are associated with 3-month mortality of 3%, 9%, and 31%, respectively.[104] Further validation of this model, as well as confirmation that patients identified as high risk would, indeed, benefit from earlier surgical intervention, are required before use of this model in decision-making can be considered standard of care.

Empyema management was evaluated in nearly 4100 patients in the New York State Inpatient Database from 2009 to 2014.[107] The initial modality of treatment was as follows: chest tube (68%), VATS (19%), or open surgical intervention (14%). Patients who initially received a chest tube were older and had more comorbidities and higher levels of shock. For patients initially receiving a chest tube, nonsurgical management was achieved in 56% of patients, while 85% of patients receiving an initial VATS were managed successfully. In patients receiving surgical therapy initially, the hospital mortality, 30-day readmission rate, and need for another intervention were all significantly lower. However, there were limitations of this study, including a healthier patient population undergoing VATS. Furthermore, the study did not take into account patients who received tPA and DNAse.

■ Tuberculous Pleurisy

Geography plays a pivotal role in determining the pretest probability of a tuberculous pleural effusion. In the developing world, tuberculosis (TB) accounts for 30% to 80% of all pleural effusions and may result from primary infection or reactivation of disease.[115,116] This percentage estimate drops to roughly 1% in developed countries. Interestingly, pleural effusions are seen in up to 30% of patients in the developing world who present with pulmonary TB, versus only 3% to 5% in developed countries.[117] One caveat to this rule in the developed world is a higher prevalence of disease in persons with HIV coinfection.[117]

Two mechanisms for development of a tuberculous pleural effusion have been postulated. One suggests a T helper cell–mediated delayed hypersensitivity reaction related to the entry of mycobacterial antigen into the pleural space from a ruptured subpleural caseous foci.[118] Another suggests a paucibacillary infection of the pleural space that likely spread from an adjacent parenchymal lesion.[117,119] In any event, the clinical presentation is often acute or subacute, with fever (75%), pleuritic chest pain (50%–75%), and a nonproductive cough (70%–75%). Other symptoms include night sweats (50%), dyspnea (50%), and weight loss (25%–85%).[120,121]

Tuberculous effusions are typically unilateral and encompass less than two-thirds of the hemothorax. Chest CT scans can detect parenchymal changes consistent with active pulmonary TB in up to 80% of patients.[122] Sampling of the effusion typically demonstrates a lymphocyte predominance (>60% lymphocytes), although a neutrophilic predominance exists early in the disease course. Hence, in the proper clinical setting the clinician should still consider TB. Other pleural fluid chemistry characteristics include protein concentrations greater than 3g/dL in 55% to 77% of cases, and glucose and pH levels that mirror those of serum.[123,124]

Adenosine deaminase (ADA) can be a useful tool to support a diagnosis of TB. In endemic areas, a lymphocytic predominant effusion with an ADA >40 confirms the diagnosis in more than 90% of patients after a single thoracentesis.[120,121] However, it should be noted that ADA may be elevated in other diagnoses (e.g., lymphoma).[125,126] An ADA level of <40 adequately excludes the diagnosis in high-prevalence settings.

Pleural fluid staining for acid-fast organisms has a low yield (frequently <20%) except in the presence of concomitant HIV infection.[126] Pleural fluid culture sensitivity has traditionally been reported to be less than 50%; however, with use of liquid culture the yield may approach 75%.[127,128] Although sputum culture is positive in only 4% of patients with isolated pleural TB, the yield is >50% in patients with parenchymal infiltrates; when combined with pleural fluid cultures, a diagnosis may be established in 79% of cases.[129] In cases where a diagnosis is not achieved through thoracentesis and sputum culture, closed or ultrasound-guided pleural biopsy can increase the diagnostic yield to 82%–92%.[130] At least six pleural biopsies should be obtained, with samples sent for acid-fast stain, culture, and histopathologic inspection for granulomata.[131]

Without treatment, a tuberculous effusion typically undergoes slow resolution; however, an untreated patient has a 65% chance of developing active pulmonary or extrapulmonary TB in the next 5 years.[126,132,133] Treatment of tuberculous pleurisy is the same as for pulmonary tuberculosis, with a four-drug regimen for susceptible organisms. Consultation with an infectious disease expert is recommended in managing patients who reside in, or have emigrated from, regions with high levels of drug resistance.[134] Two-thirds of patients have residual pleural thickening, which can result in trapped lung and dyspnea due to a restrictive ventilatory defect. Complex or loculated effusions, long duration of symptoms prior to therapy, and CT evidence of extrapleural fat proliferation have been identified as risk factors for pleural thickening at 1 year.[135]

■ Other Infectious Etiologies

Acute viral respiratory infections may be associated with transient pleural effusions and likely account for a higher percentage of effusions than is generally appreciated.[136] In one study of patients with signs and symptoms of a lower respiratory tract infection and a positive viral PCR, 20% of patients had pleural effusions.[137] Pleural effusions may be seen in up to 62% of patients with adenovirus pneumonia,[138] endemic influenza, and avian influenza (H1N1) influenza, as well as endemic coronavirus and SARS-CoV-2.[139–141] Effusions due to viral infections are typically exudates with a mononuclear cell predominance.[142] Bacterial superinfection should be ruled out in patients with a pleural effusion temporally related to a viral infection.

Fungal infections may lead to pleural effusions, particularly in an immunocompromised host, and are typically caused by pleural seeding from a fungal pneumonia or other site of infection. Commonly implicated pathogens include *Candida*, *Aspergillus*, *Blastomycosis*, and *Coccidioides* species.[143,144] *Coccidioides*, in particular, has the ability to spread from an acute pulmonary infection to the pleural space in up to 15% of patients hospitalized with the infection.[145,146] The pleural fluid in acute coccidiomycosis infection is classically exudative and rich in eosinophils.[145,146] *Cryptococcus* and *Histoplasma capsulatum* rarely produce pleural effusions, and effusions due to *Histoplasma* may be attributed to fibrosing mediastinitis.[147,148]

■ Pulmonary Embolism

Pulmonary embolism (PE) is estimated to be the fourth leading etiology of pleural effusion in the United States.[149] Pleural effusions occur in 35% to 47% of patients with PE, and most are unilateral, typically occupying less than half the hemithorax.[150] The pathogenesis of pleural effusion associated with PE is unknown, but it is believed to be related to a cascade of events involving occlusion of the artery leading to ischemia distal to the embolus, and cytokine release leading to increased vascular permeability.[150–152] This, in turn, leads to increased fluid formation in the pleural space and overwhelming of the capacity of the lymphatic vessels to remove the fluid.[153]

The presence of unilateral, pleuritic chest pain in a patient with a pleural effusion should raise suspicion of PE. Pleural fluid is exudative and bloody (>10,000 RBC/μL) in approximately two-thirds of patients. Pleural fluid eosinophilia is seen in up to one-third of patients and may provide a clue to etiology.[150] Reabsorption of pleural fluid after initiation of anticoagulation typically occurs within 7 to 10 days in patients without radiographic evidence of infarction, and in 14 to 21 days in those with this finding.[154] It is reasonable to forego thoracentesis in most patients with small effusions in the setting of proven PE unless there are atypical features suggesting an alternative diagnosis (e.g., fever, large effusion). In particular, an increase in the size of the effusion after initiation of anticoagulation should prompt thoracentesis to evaluate for secondary hemothorax.

■ Hemothorax

Many pleural effusions have an appearance of being “bloody,” as a pleural fluid hematocrit >5% may have a similar appearance to blood.[150,155] To meet criteria for hemothorax, however, the pleural fluid hematocrit must be >50% of the simultaneous peripheral blood hematocrit.[152] If the pleural fluid is not spun for a hematocrit, one can estimate the pleural fluid hematocrit by dividing the pleural fluid RBC count by 100,000. If the pleural fluid appears bloody and the hematocrit is <50%, it is considered a hemorrhagic effusion but not a true hemothorax.

The majority of cases of hemothorax are related to blunt or penetrating trauma, or to thoracic procedures and surgery (Table 76-7).[152,156] Rarely, spontaneous hemothorax occurs from either a torn adhesion between the parietal and visceral pleura, rupture of a vascularized bullae in the lung, deposits of endometrial tissue in the thorax (catamenial hemothorax), or congenitally aberrant vessels between the parietal pleura and bullae.[155] In instances of trauma, initial evaluation with ultrasound in the emergency department has a sensitivity of 92% and a specificity of 100% for detecting hemothorax.[157]

Tube thoracostomy is the best first step to drain a hemothorax. A large-bore (at least 28Fr) tube has traditionally been recommended to prevent obstruction of the tube from clots; however, more recent

TABLE 76-7 Causes of Hemothorax

Condition	Comments
Coagulopathy and bleeding diatheses	Hemothorax due to primary coagulopathies, thrombocytopenia, anticoagulant therapy, or systemic and intrapleural fibrinolytic therapy rarely occur
Pneumothorax and ruptured lung bullae	Hemothorax uncommon with spontaneous pneumothorax but can occur especially with ruptured lung bullae
Neurofibromatosis	Rupture of friable vasculature in patients with neurofibromatosis may occur by vascular invasion or arterial dysplasia
Arteriovenous malformations	Arteriovenous malformations rarely bleed into the pleural space with one-half of instances related to Osler–Weber–Rendu disease
Aneurysms	Dissection or rupture of a major intrathoracic artery is a common and usually clinically apparent cause of hemothorax; most commonly aortic but also pulmonary vasculature
Ehlers–Danlos disease	Associated with internal mammary artery rupture
Connective tissue diseases	Rare reports
Extramedullary hematopoiesis	Rare reports
Endometriosis	Varying degrees of hemorrhagic effusions or hemothorax
Exostoses	Formation of new bone on the surface of existing bone creates sharp bony edges that can erode adjacent vascular structures and cause hemothorax
Postpartum	Related to thoracic pressure changes during labor straining

data suggest no difference between a 28Fr and 20- to 22Fr tube with respect to successful drainage or complications.[158] Surgical exploration is indicated for persistent bleeding or shock and is typically a definitive procedure.[159–162] Clinicians must be mindful of retained and loculated collections of blood, as these can be a nidus for infection and the development of fibrothorax and resultant trapped lung.[163]

Vasculitis

Pleural effusions have been reported in multiple vasculitides, including granulomatosis with polyangiitis (GPA), eosinophilic granulomatosis with polyangiitis (EGPA), giant cell arteritis, and Behçet disease.[164–166] In most of these disorders, pleural effusion occurs in a minority of the cases and is a late clinical manifestation. Reports of pleural fluid evaluation in vasculitides are rare, but they typically describe nonspecific exudates. EGPA has been reported as having increased eosinophils.[167,168] Treatment of the effusion includes systemic immunosuppression, although if disease is advanced, more invasive management may be required.[166]

Superior Vena Cava Syndrome

Pleural effusion complicates superior vena cava (SVC) syndrome in 6% to 70% of cases.[169] SVC syndrome occurs when there is either external compression or intrinsic blockage of the SVC. It is seen most commonly in patients with mediastinal malignancies, but it has also been described in neonates after placement of central venous catheters.[169–174] The effusion is exudative and may be chylous (18%). It is relieved with resolution of SVC syndrome.[171,172,174]

Systemic Lupus Erythematous

Pleurisy is one of the 11 diagnostic criteria for systemic lupus erythematous (SLE) and occurs in 34% to 60% of patients during their disease course.[175] Approximately 80% of patients have other organ involvement, and 16% will have concomitant pericardial effusions.[176] Pleural inflammation may manifest as pleuritic pain in the absence of pleural effusion, but more commonly presents with either unilateral or bilateral pleural effusions. The presence of pleuritic pain has been reported to be a poor prognostic indicator, with a mean survival of less than 4 years.[177] Because patients are commonly on immunosuppressive agents, an infectious etiology must also be considered.[178]

The typical pleural fluid profile is shown in Table 76-8. Pleural fluid ANA is usually positive, but it does not provide incremental diagnostic value beyond that of a positive serum ANA.[178,179] Occasionally, lupus erythematous cells can be identified on cytologic examination of the fluid.

Nonsteroidal anti-inflammatory drugs are the initial treatment of choice, with corticosteroids reserved for refractory cases. Relapses occur in approximately 13% of patients.[176] In rare instances where effusions are large and refractory to treatment, pleurodesis may be necessary.[180] Lupus pleuritis may also rarely progress to fibrothorax and trapped lung if the disease course is not altered by treatment.[181]

Rheumatoid Arthritis

The most common thoracic manifestation of rheumatoid arthritis (RA) is pleural disease, including pleural thickening and pleural effusion that may occur at any time throughout the disease course.[180,182,183] Pleural effusions occur in up to 20% of patients, with 80% occurring in men.[184] Patients are most commonly asymptomatic from the effusion but often have concurrent evidence of active arthritis, rheumatoid lung lesions, or subcutaneous nodules.[181,182,184] The pleural profile is listed in Table 76-8, but clinicians must always rule out an infectious etiology, given that pleural fluid glucose and

TABLE 76-8 Pleural Fluid Test Results in Common Autoimmune Causes of Pleuritis

Finding	Lupus Pleuritis	Rheumatoid Arthritis
Appearance	Clear	Variably serous, purulent, milky, hemorrhagic
Protein	Low in exudative range	High in exudative range
Glucose	Similar to serum	Often low <30 mg/dL
Leukocytes	3–5000/μL	Usually $<10{,}000$/μL
Complement	Low	Low
Immune complexes	High	High
PF ANA	Positive	Variable
LDH	Twice upper limits of normal for serum	High
Rheumatoid factor	Low	Elevated

PF, pleural fluid; LDH, lactate dehydrogenase; ANA, antinuclear antibody.

pH are commonly low. Low pleural fluid glucose is due to impaired glucose transport through the pleura,[185] and pleural fluid glucose levels of <30 mg/dL are seen only in patients with RA or empyema.

Most effusions related to RA resolve spontaneously or with systemic disease-modifying medication, although a recent study suggested the presence of an effusion as an independent marker for mortality.[186] Large, refractory effusions should be drained, as without intervention fibrothorax and trapped lung may result.[181] Chronic rheumatoid arthritis–related effusions are also one of the most common causes of "cholesterol" or "pseudochylothorax" effusions.[187]

Other connective tissue diseases also can manifest with pleural effusion. Patients with Sjögren syndrome commonly develop recurrent pleuritic chest pain, but only 9% of patients have pulmonary manifestations, and 1.2% have pleural effusions.[188] Up to 7% of patients with systemic sclerosis may have a pleural effusion, which is typically lymphocytic-predominant.[175] Mixed connective tissue disease commonly involves the pleural space, with 35% of patients experiencing pleurisy and 50% having a pleural effusion.[189] Ankylosing spondylitis, dermatomyositis, and polymyositis have rarely been reported as complicated by exudative effusions.[190–194]

■ Sarcoidosis

Sarcoidosis is a multisystem disease, the hallmark of which is the presence of noncaseating granulomas.[195,196] Pleural involvement is infrequent, with the majority of published clinical series suggesting a prevalence of 1% to 2%.[196] Patients with sarcoidosis-related effusions tend to have both pulmonary parenchymal and extrapulmonary disease.[196–198] Effusions are typically unilateral, and the majority are exudative, although transudative effusions also have been described.[195] The effusions tend to be lymphocytic predominant, with a high CD4/CD8 ratio.[195]

A definitive diagnosis of sarcoidosis-related pleural effusion requires demonstration of noncaseating granulomas on pleural biopsy and exclusion of infectious etiologies, such as TB and fungal disease.[199] Administration of corticosteroids leads to resolution of the fluid in as little as 2 weeks, but reports have also described spontaneous resolution without therapy.[200]

■ Pancreatitis and Pancreatic Fistulae

Pleural effusions are frequently present in patients hospitalized with acute pancreatitis, with a prevalence approaching 50% in some case series.[201–203] The mechanism of pleural fluid formation in pancreatitis is attributed to multiple etiologies, including the release of proinflammatory mediators from the pancreas into the circulation, transdiaphragmatic transit of parapancreatic inflammatory exudates, lipolysis of mediastinal fat, and early formation of pancreaticopleural fistulae.[201] The pleural fluid is exudative and often has a low pH and high amylase.[204,205] It should be remembered that elevated pleural fluid amylase can also be seen in patients with TB, esophageal rupture, and malignancy. The presence of a pleural effusion is associated with more severe pancreatitis, and patients may have a mortality of up to a 30%.[202,203] The majority of pleural effusions (68%) are left-sided; bilateral (22%) and right-sided (10%) effusions occur less commonly.[206,207] Effusions are typically small, exudative, occasionally bloody, and characterized by a high amylase (as high as 30 times the serum level).[204]

A pancreaticopleural fistula may develop when the main pancreatic duct is disrupted, leading to leakage of pancreatic enzymes through the diaphragm. Posterior disruptions of the duct can track into the retroperitoneum, then mediastinum, and, ultimately, rupture into the pleural cavity, creating a connection between the pancreatic duct and the pleural cavity.[207–210] This is more commonly seen in chronic pancreatitis, with alcohol-related pancreatitis (51%) representing the most frequent underlying cause.[209–211] Magnetic resonance cholangiopancreatography (MRCP) is the most sensitive means of demonstrating a pancreaticopleural fistula; other options include endoscopic retrograde cholangiopancreatography (ERCP) and abdominal/chest CT scanning.[207,211–213] Closure of the fistula can be achieved via medical therapy aimed at treating chronic pancreatitis or endoscopic or surgical procedures.

■ Chylothorax

The thoracic duct carries 60% to 70% of ingested fat from the intestines and contains large amounts of cholesterol, triglycerides, chylomicrons, and lymph.[214] Additionally, chyle is rich in lymphocytes and immunoglobulins.[215] The thoracic duct originates in the cysterna chyli and courses superiorly through the esophageal hiatus of the diaphragm into the thorax. It travels extrapleurally on the right side of the chest, crosses the midline at approximately the level of the fourth to sixth thoracic vertebrae, and terminates in the cervical region in the subclavian vein. This "textbook" path, however, occurs in only 65% of patients, and multiple other routes have been described.[214]

A chylothorax occurs when chyle leaks into the pleural space as a result of disruption of the thoracic duct at any point along its course. Trauma accounts for approximately 50% of cases and can be a consequence of thoracic surgery, neck surgery, blunt or penetrating chest trauma, or instrumentation, such as central venous catheter or pacemaker insertion.[214,216–221] Disruption of the duct subsequently leads to buildup of chyle in the mediastinum, with subsequent rupture of the mediastinal pleura and chylothorax.[222] Malignancy, most commonly lymphoma, is the most frequent nontraumatic etiology.[223] Other less common nontraumatic etiologies include yellow nail syndrome, amyloidosis, retrosternal goiter, lymphangioleiomyomatosis, and sarcoidosis (Table 76-9).

Chylous effusions are most commonly unilateral, but they may be bilateral in 20% of cases.[223] The laterality of the effusion is dictated by whether the site of disruption is below or above the T5 vertebral body, where the thoracic duct typically crosses over from the right to the left side. Although chylous fluid classically has a characteristic milky appearance (Fig. 76-2) in patients eating a standard diet, this characteristic is often lacking in fasting patients. A pleural fluid triglyceride level of >110 mg/dL is considered diagnostic, while a level <50 mg/dL excludes the diagnosis.[224] If the pleural fluid triglyceride level is between 50 and 110 mg/dL, chylomicron analysis is indicated, although not all centers can perform this test.[225] In one

TABLE 76-9 Causes of Chylothorax

Classification	Comments
Traumatic	Account for 50% of chylothoraxes with thoracic surgery most common cause. Also occur after neck surgery, central venous catheter and pacemaker insertion, blunt chest injury, traction injuries to the chest and neck, and sudden pressure changes with sneezing, vomiting, or labor and delivery.
Nontraumatic	Lymphoma has decreased in incidence to 11% because of earlier lymphoma diagnosis. Less common causes include congenital or acquired lymphatic disorders, constrictive pericarditis, SVC syndrome, lymphangiomatosis, lymphangiectasias, lymphangioleiomyomatosis, Noonan syndrome, yellow nail syndrome, Down syndrome, granulomatous infections, and thyroid goiter.
Idiopathic	Small number idiopathic despite a complete diagnostic evaluation.

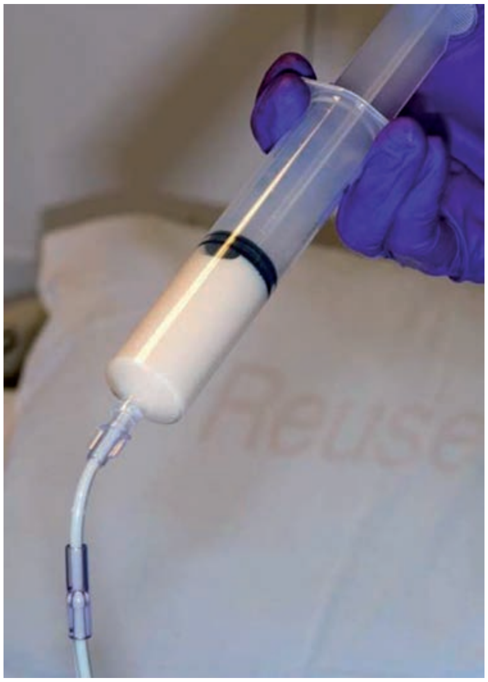


Figure 76-2 Sample of pleural fluid from a patient with chylothorax.

series, detection of chylomicrons was seen in 14% of patients with a triglyceride level less than 110.[226] If chylomicron analysis is not available, repeat pleural fluid triglyceride measurement after ingestion of a high fat meal can sometimes confirm the diagnosis.

Once the diagnosis has been established, continued drainage of the pleural space via chest tube or repeated large-volume thoracentesis should be avoided, as this can result in depletion of protein and lymphocytes, potentially leading to malnutrition and immunosuppression. Conservative measures to decrease the formation of chyle by administration of a low-fat/high medium chain triglyceride diet or total parenteral nutrition can lead to resolution of the leak in some cases of traumatic chylothorax, and it may take up to 2 weeks for chest tube output to improve.[227] Treatment of the underlying medical cause for chylothorax may be effective (e.g., administration of chemotherapy for lymphoma or sirolimus for lymphangioleiomyomatosis).

For those with refractory effusions, imaging to identify the site of thoracic duct disruption is often performed. This was previously accomplished using lymphangiography or lymphoscintigraphy, but magnetic resonance lymphangiography has supplanted these modalities at some centers.[228]

Thoracic duct embolization has emerged as a nonsurgical option for treating refractory thoracic duct leaks, with a success rate of up to 90% for traumatic chylothoraxes, and 50% for nontraumatic cases when performed by an experienced operator.[229] Surgical ligation of the thoracic duct is reserved for patients who fail more conservative measures and is best suited for postoperative chylous effusions. Finally, IPCs and pleurodesis may be an effective measure for both traumatic and nontraumatic cases; however, outcomes are typically better with traumatic chylothoraces, and surgery remains the treatment of choice as long as patients are good surgical candidates.[224,230]

■ Pseudochylous Effusions

Pseudochylothorax (also called “chyliform” or “cholesterol pleural effusion”) derives its name from the often milky appearance of the pleural fluid, similar to chylothorax. Pseudochylothorax, however, results from a markedly elevated cholesterol content and does not contain chylomicrons.[231]

Pseudochylothorax is usually the result of an exudative effusion that remains in the pleural space for an extended period of time—often 5 years or longer—with gradually increasing cholesterol concentrations (most commonly, high-density lipoprotein) due to impaired transfer out of the pleural space.[232,233] The most frequent causes are TB and rheumatoid pleuritis; rare causes include infection (e.g., echinococcosis, paragonimiasis), neoplasia, trauma, and prior pericardial injury (e.g., following cardiac surgery).[231,234–236] Most pseudochylous effusions are unilateral and accompanied by pleural thickening.

Pleural fluid analysis demonstrates a high cholesterol content (>200 mg/dL) and may have cholesterol crystals seen on microscopy. Triglyceride levels are typically below 110 mg/dL.[231] Pleural biopsy may occasionally reveal the etiology, but the yield is quite low.[237] Treatment is directed at the underlying etiology, such as TB or rheumatoid arthritis. Most patients are asymptomatic, but large effusions causing dyspnea may be addressed with thoracentesis, pleurodesis, or, in cases of trapped lung, decortication.[237,238]

■ End-Stage Renal Disease

Approximately 50% of patients receiving hemodialysis with acute respiratory complaints have pleural effusions when evaluated by CT scans.[238,239] The most common causes of pleural effusion in this patient population mirror those of the general population and are related to congestive heart failure, pneumonia, tuberculosis, malignancies, and volume overload.[240]

Pleural effusions can also develop as a consequence of uremia.[241,242] The mechanism by which uremia leads to pleural inflammation and effusion is not well understood, but it likely shares a similar pathogenesis with uremic pericarditis. Effusions may be unilateral or bilateral and can be large, occupying 50% or more of the pleural cavity.[241] Pleural fluid is exudative, lymphocytic predominant, and bloody nearly half the time. As there are no characteristic features, uremic pleuritis is a diagnosis of exclusion.[241]

Treatment involves initiation or augmentation of hemodialysis, which leads to disappearance of fluid in 52% to 75% of patients.[241,243–247] Rarely, decortication is necessary for patients who develop pleural fibrosis with trapped lung.[248]

■ Post–Cardiac Surgery

At least 40%, and up to 63%, of patients who undergo coronary artery bypass graft (CABG) surgery develop a pleural effusion in the first 28 days post-surgery as a consequence of the surgery itself, in the absence of complications.[249–251] While effusions post-CABG have been most widely reported, the incidence of effusion after valve-only surgery can approach 45%.[252]

The pathogenesis of these effusions is likely related to some combination of the effects of topical cardiac cooling, surgical interruption of the lymphatic channels, direct surgical injury of the pleura, and pericarditis.[251,253] The effusions are typically left-sided and occupy less than 25% of the hemithorax.[251,253] Most effusions resolve spontaneously. If effusions persist, enlarge, or cause dyspnea, it is reasonable to pursue a thoracentesis to exclude other etiologies or for symptomatic relief. If thoracentesis is required, the minority of patients will require more than one or two procedures. Although some clinicians routinely use nonsteroidal anti-inflammatory medications or corticosteroids, data supporting their use are lacking. Pleural fluid present within the first 30 days of surgery is typically bloody and neutrophilic and may contain >10% eosinophils. Late-developing effusions are typically nonbloody and have a lymphocytic predominance.[251,253,254]

An alternative cause for pleural effusions developing in the early post-operative period is postcardiac injury syndrome (Dressler syndrome), which is characterized by pericarditis, pulmonary infiltrates, and pleural effusions.[255–257] In contrast to the more commonly occurring asymptomatic effusions described above, patients who develop this syndrome are often febrile and experience chest pain. The presence of a pericardial or pleural friction rub is a clue to the diagnosis. Pleural effusions are usually small and left-sided, hemorrhagic, and neutrophil-predominant in the acute phase, evolving to lymphocyte-predominant over time.[258] Nonsteroidal anti-inflammatory drugs are the initial treatment of choice. Corticosteroids are used in more severe or refractory cases.

■ Meigs Syndrome

Meigs syndrome is defined by the presence of pleural effusions and ascites in association with an ovarian fibroma or fibrothecoma.[259,260] Pleural fluid accumulation in Meigs syndrome is postulated to result from efflux of ascites from the peritoneal cavity into the pleural space via diaphragmatic rents. The mechanism responsible for development of ascites is a matter of conjecture. One theory suggests that inflammatory cytokines and growth factors, possibly produced by the ovarian tumor, lead to vascular permeability within the peritoneal cavity.[261] The finding of high levels of vascular endothelial growth factor (VEGF) and interleukin 6 in serum, ascites, and pleural fluid in patients with Meigs syndrome support this hypothesis.[262] Weeping of fluid from the tumor itself also may play a role. Elevated CA-125 levels have been detected in patients with Meigs syndrome, creating diagnostic uncertainty by raising suspicion for a malignant ovarian tumor.[263]

As with most pleural effusions that result from ascites, the pleural effusion in Meigs syndrome is most commonly unilateral and right-sided, occupying more than one-third of the hemithorax in two-thirds of cases.[262] Presenting symptoms include dyspnea, abdominal distention, fatigue, and weight loss. The published literature contains scant information on pleural fluid characteristics but suggests that most effusions due to Meigs syndrome are exudative. The finding of a transudative effusion does not, however, exclude this diagnosis.[262]

Treatment of Meigs syndrome centers on surgical removal of the responsible ovarian tumor, which is considered curative, given the benign nature of the tumors associated with this syndrome. Pleural effusion and ascites typically resolve within several weeks of tumor resection.

MANAGEMENT OF RECURRENT AND PERSISTENT EFFUSIONS

Independent of etiology, many nonmalignant pleural effusions are responsive to initial drainage and treatment of the primary disorder. However, there exists a subset of patients whose effusions persist or recur despite conservative management. In these instances, additional intervention(s) may be required.

■ Repeat Thoracentesis

Repeat thoracentesis under ultrasound guidance is typically the first-line option. This can serve as a destination therapy in patients who derive symptomatic improvement with drainage and have slowly reaccumulating effusions, and also for patients with a short life expectancy. Additionally, a repeat thoracentesis affords the clinician another opportunity to make a minimally invasive diagnosis if the etiology is still in question. Repeated thoracenteses should be avoided in asymptomatic patients and those who did not experience relief with initial drainage. For those who do benefit, but who require more than two or three thoracenteses in a relatively short time, a more definitive therapy (e.g., pleurodesis or IPC) should be considered.

■ Pleurodesis

Pleurodesis is defined as obliteration or ablation of the pleural cavity through induction of pleural inflammation and fibrosis.[264,265] This can be achieved via chemical (e.g., talc) or mechanical (e.g., manual abrasion) means. Chemical pleurodesis can be performed via a chest tube (i.e., talc slurry) or thoracoscopically (i.e., poudrage/insufflation), while mechanical pleurodesis is performed only via surgical intervention. Chemical pleurodesis utilizes a variety of sclerosing agents, but the most commonly used presently is talc. Treatment failure rates for patients with malignant pleural effusion are similar for chemical pleurodesis administered via chest tube and VATS; however, comparative efficacy data are lacking in patients with nonmalignant effusion.[265,266]

Patients best suited for pleurodesis are those who experience symptomatic improvement following drainage, have expandable lung, or experience rapid reaccumulation of fluid, and for whom indwelling pleural catheter is deemed to be an inappropriate or less suitable alternative. Case series have documented successful management in patients with such diverse etiologies as peritoneal dialysis-related effusions,[267,268] yellow nail syndrome,[269] chylothorax,[270,271] nephrotic syndrome,[272] heart failure,[46,273,274] and hepatic hydrothorax.[62,275–277] The success rate of pleurodesis in NMPEs ranges from 47% to 80%, depending on the case series and etiology, with hepatic hydrothorax having a higher rate of failure and a high risk of infectious complications.[62,278–280] Importantly, the pleural space needs to be fully (or at least ~90%) drained and the parietal and visceral pleura apposed for optimal results. This may be difficult to achieve with high-volume, rapidly reaccumulating effusions that often characterize hepatic hydrothorax. Some centers advocate the use of multiple chest tubes and large-volume paracentesis (for patients with concurrent ascites that is deemed to be the source of the pleural effusion) in order to keep the pleural space as dry as possible when pleurodesis is performed.

■ Indwelling Pleural Catheter

IPCs are tunneled under the skin and provide a source of intermittent drainage of the pleural space that obviates the need for repeated thoracenteses. They remain in place for several weeks to months and ideally are removed once fluid accumulation has ceased. A systematic review of 13 studies encompassing 325 patients with benign pleural effusions found that spontaneous pleurodesis occurred following IPC placement in 51% of patients, with slightly higher rates in noncardiac causes. Complications occurred in 17% of patients, including empyema and cellulitis.[48,281]

FUTURE DIRECTIONS

The last decade has seen a tremendous increase in our understanding of nonmalignant pleural effusions, primarily resulting from large, multicenter, randomized trials. There are still many unanswered questions, however. For example, pleural infection affects a broad group of patients with a diverse spectrum of comorbidities. We need to examine if current predictive models, such as the RAPID score[104] or chest ultrasound, can be used to select patients for medical versus early surgical therapy.

In an ongoing trial (ISRCTN18192121), investigators are comparing early intrapleural TPA/DNase versus early VATS in patients with pleural infection.[282]

The optimal management for effusions due to CHF and hepatic hydrothorax also needs to be investigated, given that these disorders comprise a significant healthcare burden and are associated with extremely high mortality rates.[5,282]

As we better understand the molecular mechanisms of pleural fluid formation, it may be possible to directly inhibit formation or stimulate resorption. The formation of multicenter collaborative groups whose focus is on pleural disease will certainly contribute to high-quality research, improve our understanding of disease and treatment, and ultimately improve the care of our patients.[283,284]

CHAPTER 77

Malignant Pleural Effusions

Jeffrey C. Thompson
Kevin C. Ma

INTRODUCTION

A malignant pleural effusion is defined by the accumulation of fluid in the presence of malignant cells or tumor tissue in the pleural space. Malignant pleural effusions are common, affecting approximately 15% of patients with malignancies, and account for more than 125,000 hospitalizations in the United States annually, with estimated healthcare costs of greater than $5 billion per year.[1,2] The incidence of malignant pleural effusions is expected to rise as a result of the increasing global cancer prevalence and development of more effective systemic therapies.[3] The presence of a malignant pleural effusion is a hallmark of advanced-stage disease and denotes a poor overall prognosis, with a median survival ranging between 3 and 12 months depending on the primary tumor type.[4] Although some patients may be asymptomatic, the majority develop dyspnea at rest with associated reduced quality of life.[5] Despite advancements in understanding the pathophysiology of malignant pleural effusions and remarkable progress in cancer treatments over the last decade, management strategies for malignant pleural effusions remain palliative, with the goal of relieving patient symptoms and minimizing the need for repeat invasive procedures.

ETIOLOGY

Although any malignancy may involve the pleura, epithelial malignancies account for approximately 80% of malignant pleural effusions, with lung and breast cancer representing the majority of cases (Table 77-1). Lung cancer is the leading cause of a malignant pleural effusion, which is present in an estimated 15% of lung cancer patients at diagnosis and develops in up to 50% of patients during the course of their disease. Effusions can occur with any lung cancer histology but are most frequent in adenocarcinomas.[6,7] Breast cancer is the second leading cause of a malignant pleural effusion. Approximately 7% to 11% of breast cancer patients will develop a malignant effusion, and these effusions are typically unilateral and ipsilateral to the primary tumor site.[8–10] Other carcinomas that commonly cause malignant pleural effusions include malignancies of gastrointestinal and ovarian origin. Lymphomas, including both Hodgkin and non-Hodgkin lymphomas, are the most common hematologic malignancies associated with malignant pleural effusions and account for approximately 7% to 16% of all cytologically confirmed malignant pleural effusions.[11,12] Patients with a malignant pleural effusion due to lymphoma typically have mediastinal lymph node involvement.[13] The primary origin of the tumor is not identified in approximately 10% of malignant effusions.[2,11] Malignant mesothelioma is the most common primary pleural tumor to cause a malignant pleural effusion; the incidence varies by geographic region and is highly correlated with exposure to asbestos.

TABLE 77-1 Most Common Primary Malignancies Among Patients with a Malignant Pleural Effusion (n = 126,825)

Cancer Type	Frequency
Lung	37.8%
Breast	15.2%
Hematologic	11.2%
Gastrointestinal	11.0%
Gynecologic	9.0%
Other	15.8%

Data from Taghizadeh N, Fortin M, Tremblay A. US Hospitalizations for Malignant Pleural Effusions: Data From the 2012 National Inpatient Sample. Chest. 2017;151(4):845–854.

Patients with malignancies may also have alternative causes for a pleural effusion. Effusions that are not the direct result of neoplastic involvement of the pleura but are still related to the primary tumor are termed *paramalignant effusions*.[14] For example, bronchial obstruction from a tumor may lead to postobstructive atelectasis resulting in a pleural effusion. These patients may also develop a postobstructive pneumonia producing a parapneumonic effusion. The hypercoagulable state of malignancy increases the incidence of pulmonary embolism in cancer patients, which is a common cause of exudative effusions. Other considerations include obstruction of the thoracic duct causing a chylothorax, cachexia leading to hypoalbuminemia and low plasma oncotic pressure, trapped lung as a result of an inflammatory pleural peel or extensive tumor involvement of the visceral pleura, and the impact of systemic treatments such as chemotherapy and radiation therapy ultimately leading to pleural effusions. Furthermore, concurrent comorbidities such as congestive heart failure may also account for pleural effusions in patients with malignant disease.

PATHOGENESIS

A pleural effusion develops when pleural fluid production exceeds reabsorption. The parietal pleura has lymphatic stomata: 2- to 12-µm openings between parietal pleura mesothelial cells that ultimately drain into lymphatic channels, with flow directed toward the mediastinal lymph nodes. This lymphatic system is the primary means by which pleural fluid and proteins are reabsorbed,[14] and the network has the ability to significantly augment lymphatic flow in response to increased pleural fluid production.[15] A pleural effusion develops as a consequence of substantial increases in pleural fluid production, impaired lymphatic drainage, or a combination of these two factors. In malignant pleural effusions, cancer cells can infiltrate this lymphatic system anywhere between the parietal pleura and mediastinal lymph nodes, resulting in the development of a pleural effusion.

Autopsy studies of lung cancer patients have shown that tumor cells metastasize through the pulmonary vasculature with subsequent embolization to the ipsilateral visceral pleura.[1,16] Dissemination to the parietal pleura occurs from direct extension from the visceral pleura through pleural adhesions or by exfoliation into the pleural cavity.[1,17] Pleural metastases may also develop through lymphangitic spread or through direct invasion of the pleura by the primary tumor. However, not all patients with pleural metastases have a malignant pleural effusion, and the presence of a malignant pleural effusion has been more closely associated with carcinomatous infiltration of the mediastinal lymph nodes than the extent of pleural involvement by metastases.[1,16] Although lymphatic obstruction secondary to tumor invasion was previously recognized as the primary pathophysiologic mechanism for the development of a malignant pleural effusion based on early autopsy studies,[16,18] blockade of pleural fluid reabsorption alone is not sufficient to explain malignant pleural effusion formation. Evidence suggests that additional factors are involved since fluid accumulation and protein content in cases of malignant pleural effusions often exceed the amount expected from lymphatic obstruction alone, and malignant pleural effusions are often bloody.[19,20] Increasingly, plasma leakage through hyperpermeable pleural vascular networks leading to increased fluid production is being recognized as a primary driver for the development of malignant pleural effusions, and significant progress has been made in recent years elucidating the molecular mechanisms involved in this process.[19]

The development of a malignant pleural effusion involves a complex interplay between tumor cells and host inflammatory, mesothelial, and endothelial cells within the pleural microenvironment to stimulate pleural inflammation, tumor angiogenesis, and vascular permeability. Both tumor and host cell production of vascular endothelial growth factor (VEGF) serves a central role in the development of malignant effusions.[21–23] VEGF is a powerful angiogenic factor and potent stimulator of vascular hyperpermeability, and a number of studies have demonstrated higher VEGF levels in the effusions of patients with malignant compared with nonmalignant effusions.[24,25] In an immunodeficient mouse model, IV injections of human lung cancer cells led to pleural metastases and produced pleural effusions with high levels of VEGF, and silencing of the VEGF gene resulted in significantly decreased malignant pleural effusion formation.[22,23] However, a more recent immunocompetent mouse model of malignant pleural effusion showed that inhibition of the transcription factor nuclear factor (NF)-κB limited pleural fluid effusion formation independent of VEGF levels, highlighting the role of alternative mediators involved in pleural effusion formation.[26]

More recent evidence suggests that tumor–host interactions, through autocrine and paracrine signaling networks, promote a cascade of inflammatory and vasoactive events that culminate in pleural effusion formation. These events are triggered by paracrine signaling to host cells, mediated through distinct transcriptional programs including NF-κB and signal transducer and activator of transcription (STAT) 3, to release inflammatory and vasoactive effector molecules including tumor necrosis factor α, interleukin (IL)-6, C-C-motif chemokine ligand (CCL) 2, secreted phosphoprotein 1 (SSP-1, also known as osteopontin [OPN]), and VEGF.[21,26–29] In addition, these mediators induce activation of resident host cells and stimulate the influx of inflammatory cells that promote a feedback loop further activating inflammation, vascular permeability, angiogenesis, and tumor progression. The recruitment of myeloid cells has been implicated in the pathogenesis of malignant effusion formation through secretion of IL-1β and subsequent activation of tumor NF-κB signaling.[30,31] The T cell population in malignant pleural effusions is dominated by central memory and regulatory T cells that support an immunosuppressive microenvironment enabling immune evasion and tumor growth; however, the role of lymphocytes in the development of malignant effusions remains uncertain.[32–34] These findings outline the contemporary view of the pathophysiologic mechanisms involved in the development of malignant pleural effusions, which involve complex host–tumor cell interactions that produce vasoactive and inflammatory signaling, host cell recruitment and activation, vascular permeability, angiogenesis, and tumor progression that culminate in fluid formation. Ultimately, these mechanistic insights may pave the way for novel therapeutic strategies for the management of malignant pleural effusions.

CLINICAL MANIFESTATIONS

Dyspnea, chest pain, and cough are the most common symptoms in patients presenting with a malignant pleural effusion, with dyspnea present in greater than half of all cases.[18] Dyspnea is often debilitating and can significantly impair quality of life. Since patients with a malignant pleural effusion have advanced-stage disease, systemic symptoms such fatigue, anorexia, and weight loss are often present. However, approximately 25% of patients may be asymptomatic at the time of initial presentation.[18] Malignant pleural effusions are often in excess of 500 mL, and the majority of patients will have an abnormal chest examination including decreased breath sounds and tactile fremitus, and dullness to percussion.

The mechanisms by which pleural effusions result in dyspnea have not fully been elucidated. Two observations argue strongly against lung atelectasis as the principal cause: (1) the magnitude of improvement in lung volumes following pleural drainage is far less than the volume of fluid removed; and (2) patients with trapped lung often derive significant symptomatic improvement after pleural drainage despite inability of the lung to re-expand. Evidence from several studies suggests that the major mechanism of breathlessness relates to outward displacement of the chest wall and downward displacement (and often inversion) of the hemidiaphragm.[35–37] Conversely, the often immediate improvement in dyspnea following a therapeutic thoracentesis is likely secondary to the restoration of chest wall and diaphragmatic mechanics.

DIAGNOSTIC APPROACH

Diagnostic evaluation includes imaging, pleural fluid analysis, and various pleural biopsy modalities.

Radiologic Evaluation

Imaging techniques employed in the evaluation of suspected malignant pleural effusions include chest radiography, thoracic ultrasonography, computed tomography, magnetic resonance imaging, and positron emission tomography.

Chest Radiography

Malignant pleural effusions are typically unilateral and ipsilateral to the primary tumor, although effusions may be bilateral in approximately 10% to 15% of cases.[18,38,39] The size of malignant pleural effusions varies from small volumes that partly obliterate the costophrenic angle on plain chest radiographs to larger volumes that result in complete opacification of the hemithorax and contralateral shifting of the mediastinum. The majority of malignant pleural effusions are in excess of 500 mL, with less than 10% of patients presenting with smaller effusions.[18] Malignant pleural effusion is the most common cause of a unilateral effusion occupying greater than two-thirds of the hemithorax (Fig. 77-1).[39] In a study evaluating 163 patients with an effusion occupying greater than two-thirds of the hemithorax, malignancy was identified in 55% of cases.[40]

In patients with large effusions, the absence of mediastinal shifting to the contralateral side suggests the possibility of obstruction of the mainstem bronchus by tumor as occurs in lung cancer, fixation of the mediastinum as a result of malignant lymph node involvement, or extensive pleural involvement as occurs in mesothelioma. Other abnormalities on chest radiography that may also be appreciated in the setting of a malignant pleural effusion include the presence of a pulmonary or mediastinal mass, thoracic lymphadenopathy, and lytic or sclerotic bony lesions. However, in patients with malignant tumors other than lung cancer or lymphoma, an effusion may be the only abnormality appreciated on chest radiography.[41]

Thoracic Ultrasonography

The use thoracic ultrasonography for the diagnosis of malignant pleural effusion has evolved significantly over the last decade as a

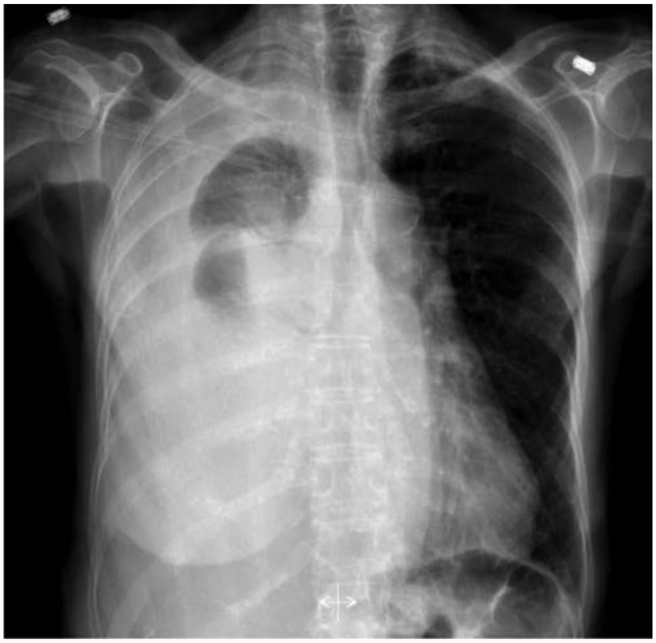

Figure 77-1 A posteroanterior chest radiograph from a patient presenting with shortness of breath showing a new, massive right pleural effusion. A thoracentesis was performed, and pleural fluid cytologic evaluation identified lung adenocarcinoma cells consistent with a malignant pleural effusion.

result of the increasing affordability, convenience, and quality of images obtained by point-of-care ultrasound devices. It enables the assessment of the size and depth of an effusion, the echogenicity of fluid, whether septations and loculations are present, and the presence of pleural thickening or nodules (Fig. 77-2).

The presence of parietal pleural thickening (>10 mm), pleural nodularity, and/or diaphragmatic nodularity or thickening (>7 mm) is highly suggestive of malignant disease, with a sensitivity and specificity of 73% and 100%, respectively.[42] Thoracic ultrasound may also be useful in the evaluation of patients with complete opacification of the hemithorax on chest radiography. In a prospective study of 50 patients with complete opacification of the hemithorax, 9 patients had no pleural effusion by ultrasonography.[43] The use of ultrasound to guide pleural procedures has been associated with improved success rates and reduced complications including lower rates of visceral organ injury and pneumothorax.[44–46] As a result, the use of ultrasound imaging to guide pleural interventions is now recommended across multiple thoracic society guidelines.[47,48] Given the low cost, safety, and efficacy profile of point-of-care thoracic ultrasound, its role in the characterization and management of malignant pleural effusions is likely to continue to expand in the coming years. The reader is referred to Chapter 29 for additional details.

Computed Tomography

Improvements in imaging technology have led to the significant expansion in the utilization of computed tomography (CT) for a variety of clinical applications.[49] The use of chest CT scans in patients with pleural effusions may unveil pathology suggestive of an underlying malignancy such as pulmonary nodules, masses, mediastinal adenopathy, or distant metastases. A contrast-enhanced chest CT scan may also provide valuable information in discriminating benign from malignant effusions. The presence of pleural nodularity, pleural thickening ≥1 cm, circumferential parietal pleural thickening, and thickening of the mediastinal pleura are strongly indicative of a malignant effusion (Fig. 77-3).[50,51]

While complete evacuation of the pleural space prior to imaging is not necessary to enhance the diagnostic accuracy of chest CT to detect pleural abnormalities,[52] it may be beneficial in detecting parenchymal or airway abnormalities in areas of atelectatic lung. A proposed CT scoring system that included the presence of any pleural lesion ≥1 cm; the presence of liver metastases, an abdominal mass, or a lung nodule/mass; and the absence of either pleural loculations, pericardial effusions, or cardiomegaly had a sensitivity of 88% and specificity of 94% for distinguishing benign from malignant effusions.[53] Although these CT features are informative when present, these imaging abnormalities do not have sufficient

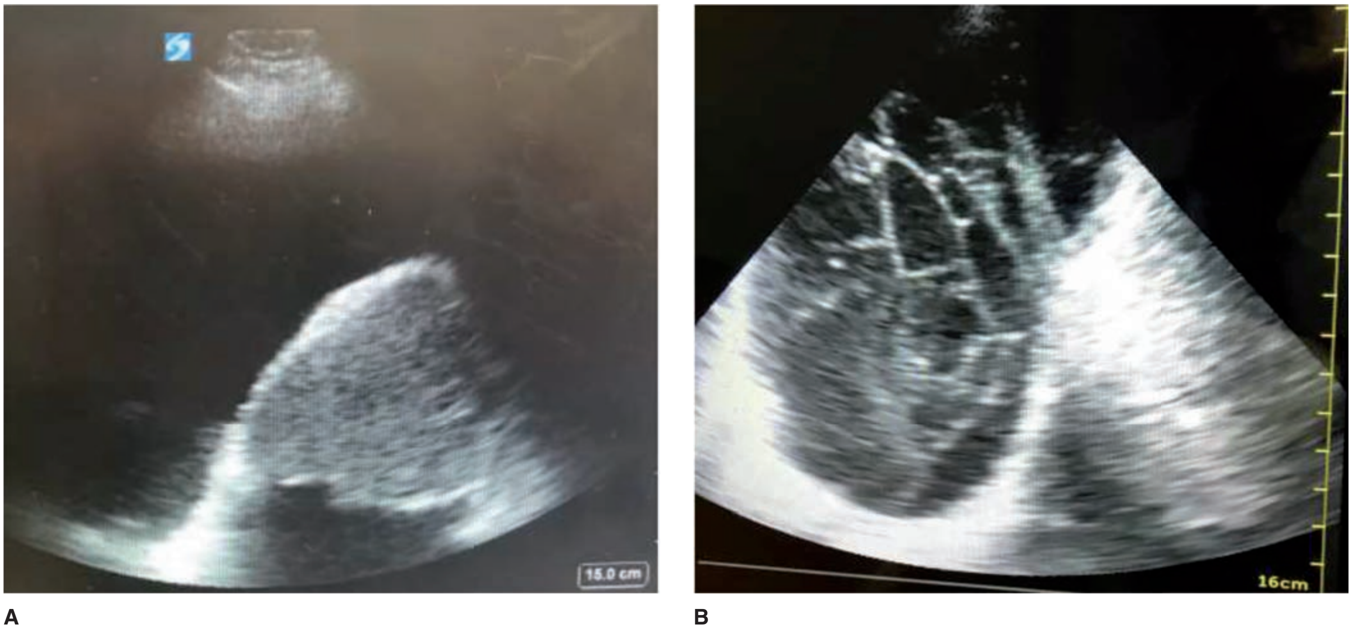

Figure 77-2 **A.** Ultrasound of the right hemithorax of a patient with a malignant pleural effusion showing a large, simple, anechoic effusion. **B.** Ultrasound of the right hemithorax demonstrating pleural fluid septations in a patient with a known right malignant pleural effusion.

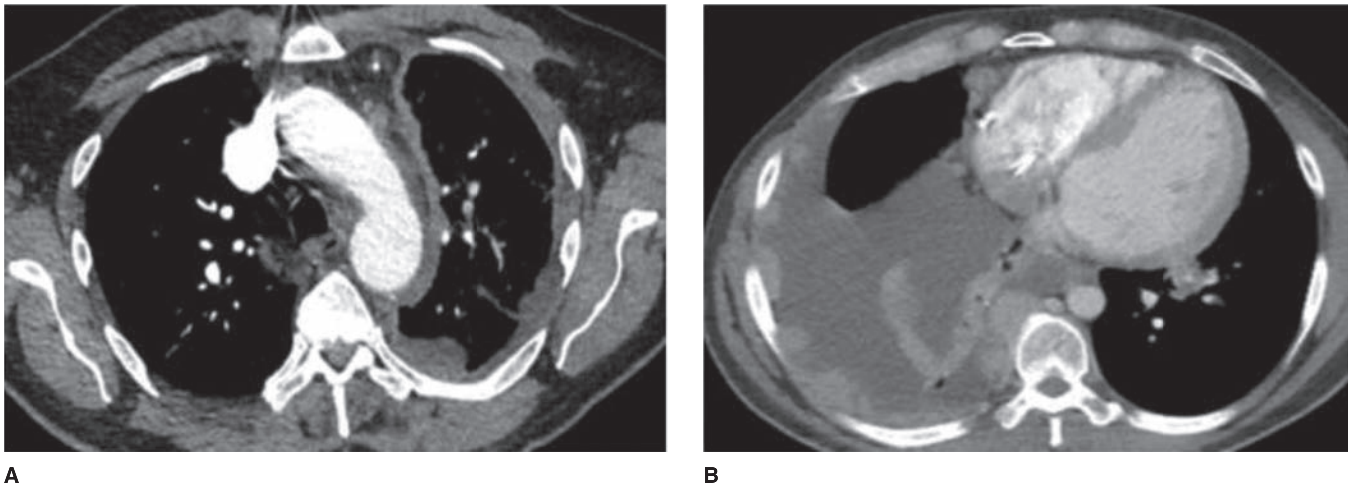

Figure 77-3 **A.** A CT scan of the chest demonstrating left mediastinal pleural thickening and pleural nodularity in a patient with a left malignant pleural effusion. **B.** A CT scan of the chest demonstrating a large right pleural effusion and multiple pleural nodules along the right pleural surface. Pleural fluid examination from a right thoracentesis revealed atypical cells suspicious for a malignant neoplasm. A subsequent CT-guided transthoracic needle aspiration of a right pleural nodule showed metastatic lung squamous cell carcinoma.

performance characteristics to obviate the need for routine cytologic examination to obtain a definitive diagnosis, and the absence of suspicious CT features should not preclude further assessment.

Magnetic Resonance Imaging

The long imaging acquisition times and susceptibility to motion artifacts have limited the use of magnetic resonance imaging (MRI) in the evaluation of pleural disease.[54,55] MRI may have a role in the diagnostic assessment and response to therapy in malignant pleural mesothelioma (MPM).[56–58] It can be particularly useful in cases of MPM when evaluating the extent of chest wall or diaphragmatic invasion by tumor, or as an alternative imaging modality in patients in whom iodinated contrast is contraindicated.[59,60] However, it currently does not have a defined role in the initial evaluation of a malignant pleural effusion.

Positron Emission Tomography

Fluorodeoxyglucose positron emission tomography (FDG-PET) scanning is a widely used imaging modality for the staging of primary malignancies; however, its role in the evaluation of malignant pleural disease remains limited. In a meta-analysis involving 14 studies and 639 patients that assessed the diagnostic usefulness of PET imaging in patients with pleural effusions, PET-CT had a sensitivity of 81% and specificity of 74% for the diagnosis of a malignant pleural effusion. False positives were frequently seen as a result of other metabolically active infectious or inflammatory lesions (e.g., prior talc pleurodesis).[61] This false positive rate severely limits the clinical utility of PET-CT in cases of suspected malignant effusion, and the moderate accuracy of PET-CT to discriminate benign from malignant effusions precludes its routine recommendation.

■ Pleural Fluid Characteristics

Ultrasound guided thoracentesis is the initial procedure of choice to sample pleural fluid in cases of suspected malignant effusion. Pleural fluid aspiration may be both diagnostic and therapeutic, often alleviating symptoms of dyspnea. It is reasonable to send pleural fluid for routine biochemical analysis (total protein, lactate dehydrogenase [LDH], and glucose), pH, cell count and differential, amylase, microbiologic studies, and cytopathology in cases of suspected malignancy. Malignant pleural effusions are almost always exudative, with transudates reported in approximately 1% to 5% of cases.[62,63] The majority of malignant effusions have a pleural fluid protein–to–serum ratio greater than 0.5. In cases where this ratio is less than 0.5, the pleural fluid LDH almost always meets exudative criteria.[64]

Malignant pleural effusions may appear serous, serosanguineous, or grossly bloody. A bloody appearance of the fluid is suggestive of malignant pleural disease.[65] Malignant pleural effusions typically have a predominance of either lymphocytes or mononuclear cells.[65] Malignancy and tuberculosis are the most common causes of an exudative effusion containing greater than 50% lymphocytes.[65,66] Although pleural fluid eosinophilia (>10%) is often seen in the setting of blood or air in the pleural space, the presence of pleural fluid eosinophilia does not exclude a malignant effusion. In a study evaluating 135 patients with an eosinophilic pleural effusion, a malignancy was identified in 35% of cases.[67]

A pleural fluid pH less than 7.3 is seen in approximately one-third of patients and is typically associated with glucose values less than 60 mg/dL. Patients with a low pH and glucose tend to have a greater burden of tumor within the pleural space, and these biochemical findings have been associated with increased diagnostic yield on cytology, decreased response to pleurodesis, and shorter overall survival.[68,69] Accurate measurement of pleural pH is dependent on sample collection and handling, with variations observed with presence of air, lidocaine, or delays in processing. Pleural fluid glucose measurements are less susceptible to variation with these factors.[70] The pleural fluid amylase level is elevated in approximately 10% of malignant pleural effusions, and the amylase is usually the salivary isoenzyme rather than the pancreatic isoenzyme. The presence of an elevated pleural fluid amylase, particularly the salivary type, in the absence of pancreatic disease or esophageal rupture is highly suggestive of malignancy.[71]

■ Cytology

The identification of malignant cells by cytologic analysis establishes the definitive diagnosis of a malignant pleural effusion in approximately 55% of cases (Table 77-2); however, there is considerable variability in diagnostic yield depending on tumor type.

For instance, exfoliative tumors such as lung adenocarcinomas and ovarian carcinomas often have diagnostic yields in excess of 70%, while lung squamous cell carcinomas and mesotheliomas are positive on cytology in less than 50% of cases.[72–74] A prospective study evaluating pleural fluid cytology in 515 patients with malignant pleural effusions demonstrated an overall sensitivity of 46%, with a sensitivity of 82% for lung adenocarcinomas, 71% for breast carcinomas, 14% for lung squamous cell carcinomas, and only 6% for malignant mesothelioma.[74]

TABLE 77-2 Sensitivity of Pleural Fluid Cytology

Primary Tumor Type	Sensitivity (%) (n = 840)[a]	 (n = 515)[b]
Overall	59%	46%
Lung	58%	56%
Adenocarcinoma	78%	82%
Squamous cell carcinoma	25%	14%
Small cell carcinoma	53%	44%
Breast	68%	71%
Hematologic	61%	40%
Gastrointestinal	48%	68%
Ovarian	70%	95%
Unknown Primary	70%	33%
Mesothelioma	27%	6%

[a] *Data from Porcel JM, Esquerda A, Vives M, et al. Etiology of pleural effusions: analysis of more than 3,000 consecutive thoracenteses. Arch Bronconeumol. 2014;50(5):161–165.*

[b] *Data from Arnold DT, De Fonseka D, Perry S, et al. Investigating unilateral pleural effusions: the role of cytology. Eur Respir J. 2018;52(5):1801254.*

The yield of cytology specimens is often limited due to the scarcity of tumor cells, inherent difficulty in distinguishing cancer cells from reactive mesothelial cells, and the experience of the cytopathologist.[75] Pleural fluid samples of at least 50 to 75 mL are sufficient to ensure the diagnostic accuracy of cytologic examination,[76–78] but minimum volumes of 150 to 200 mL may be needed when downstream molecular profiling is indicated, as in cases of lung adenocarcinomas. The diagnostic yield of cytology does not increase significantly beyond two serial measurements. In a study of 214 patients with malignant pleural effusions and an initially negative cytology specimen, a repeat thoracentesis was diagnostic in 55 cases (26%).[73] However, the yield from further repeat measurements is limited.[73,74] While cytologic examination can identify the presence of malignant cells and can typically further characterize the cells into a specific histology (e.g., adenocarcinoma) based on morphologic characteristics, further testing is often required to determine the primary site of origin.

The use of immunohistochemical stains can assist in differentiating reactive mesothelial cells from an underlying malignancy, determining the origin of the primary tumor, and identifying markers of response to targeted therapies in tumor types such as lung and breast cancer. Morphologic overlap exists between reactive mesothelial cells, malignant mesothelioma, and metastatic adenocarcinomas. Markers that identify metastatic adenocarcinomas include BerEp4, MOC-31, CEA, Bg8, and B72.3, while calreticulin, cytokeratins 5/6, WT-1, and D2-40 are mesothelial markers. It is recommended to utilize at least two of the above mesothelial markers and two epithelial markers in addition to TTF-1 when attempting to differentiate cases of epithelial malignancies from malignant mesothelioma.[79] The loss of BRCA-associated protein 1 (BAP1) staining and the homozygous deletion of the *CDKN2A*/p16 gene, detected either by fluorescence in situ hybridization (FISH) or by methylthioadenosine phosphorylase (MTAP) immunohistochemistry, are highly specific markers for mesothelioma. However, the absence of these molecular abnormalities cannot exclude a diagnosis of mesothelioma.[80] Other examples of immunomarkers that may be useful in assessing the origin of the primary tumor include TTF-1 and napsin A for lung adenocarcinomas; mammaglobin, ER/PR, GCDFP-15, and GATA-3 for breast carcinomas; and CDX-2 and CK20 for gastrointestinal malignancies.[81] Flow cytometry is a useful adjunct to pleural fluid cytology in cases of suspected lymphoma. Finally, pleural fluid immunohistochemistry can serve as a minimally invasive technique to identify biomarkers of response to targeted therapies such as the detection of anaplastic lymphoma kinase (ALK) and reactive oxygen species 1 (ROS1) fusions. In lung adenocarcinomas, detection of ALK fusions by immunohistochemistry can serve as a standalone test to determine candidacy for an ALK tyrosine kinase inhibitor. Immunohistochemistry assays to detect ROS1 fusions have a high sensitivity but limited specificity; thus, detection of a ROS1 fusion requires confirmatory testing using FISH or other molecular methodologies.[82]

Pleural fluid cytology samples may also be used for comprehensive genetic profiling. Therapeutically targetable mutations occur in 20% to 30% of patients with metastatic nonsquamous non–small-cell lung cancer (NSCLC). The list of therapeutic targets is rapidly expanding beyond *EGFR*, *ALK*, *BRAF*, and *ROS1* and now includes molecular alterations in *MET*, *RET*, *ERRB2*, and *NTRK*. In cases of advanced nonsquamous NSCLC, the National Comprehensive Cancer Network guidelines strongly recommend the use of broad molecular profiling systems that assess for the presence of these molecular alterations simultaneously.[83] Any cytology sample with adequate cellularity and preservation may be utilized for molecular testing,[84] and evidence suggests that sequencing of malignant pleural effusions has comparable diagnostic performance with corresponding tissue specimens.[85,86] In a study of 30 NSCLC patients with a malignant pleural effusion, the concordance between tissue biopsy specimens and pleural effusion samples was 87%.[86] Thus, cytologic evaluation of malignant pleural effusions offers a minimally invasive means to establish diagnostic and staging information, and provides source material to detect actionable mutations in order to match patients to appropriate personalized therapies.

■ Tumor Markers

Given the limited sensitivity of pleural fluid cytology to diagnose malignant pleural effusions, a number of studies have evaluated various molecular markers in pleural fluid to better distinguish benign from malignant effusions. A study evaluating the use of a combination of tumor markers measured in pleural fluid including carcinoembryonic antigen (CEA), cancer antigen 125 (CA-125), carbohydrate antigen 15-3, and cytokeratin 19 fragments (CYFRA 21-1) in 416 patients with benign and malignant effusions demonstrated a sensitivity of 54% for the diagnosis of a malignant effusion when utilizing cutoff values with 100% specificity for the four markers. This combination of markers had improved diagnostic accuracy in exfoliative tumors such as lung and breast adenocarcinomas (sensitivity 69%), with limited sensitivity in tumors such as lung squamous cell carcinoma and mesothelioma (sensitivity ~40%).[87] In MPM, a disease for which cytologic yield is approximately 30%, elevation in pleural fluid mesothelin level has a sensitivity of 67% and specificity of 95%.[88] An additional marker, fibulin-3, was found to have a sensitivity and specificity of 84% and 92%, respectively, for discriminating MPM effusions from effusions that were not secondary to mesothelioma.[89] Novel markers, such as analyzing cell-free DNA fragmentation patterns and the phenotyping of individual cells (e.g., identification of metabolically active cells) within pleural fluid, also have demonstrated promise in distinguishing benign from malignant effusions.[90–93] However, in order to be clinically useful for the diagnosis of a malignant pleural effusion, these assays must have a specificity of 100%, and this prerequisite often limits the sensitivity of these tumor markers. The presence of a malignant pleural effusion has important diagnostic, staging, and prognostic implications, and one would not want to incorrectly establish this diagnosis in a patient with a benign effusion. As a result, these markers have limited clinical utility but could potentially be utilized to select patients for more invasive procedures to definitively diagnose a malignant effusion. Although the aforementioned biomarkers, as well as a number of emerging biomarkers, are promising, larger studies and prospective validation are needed before they can be incorporated into clinical practice.

■ Pleural Biopsy

Pleural biopsy may be performed using a "closed" biopsy technique or via medical or surgical thoracoscopy.

Closed Pleural Biopsy

Pleural biopsies are often performed to further evaluate cytologically negative exudative effusions of unknown etiology. Closed pleural biopsies can be performed in the outpatient setting and are well tolerated, with a low rate of complications such as pain, bleeding, and pneumothorax. The diagnostic yield of blind closed pleural biopsy (non-image-guided) to diagnose pleural malignancy is low (<60%), largely secondary to the often patchy distribution of malignant pleural involvement.[66,94,95]

The use of image guidance to obtain closed pleural biopsies significantly increases diagnostic yield by enabling the practitioner to target specific pleural abnormalities, such as pleural nodularity or thickening, or to sample areas more likely to contain pleural metastases, such as the basal pleura.[96] In a study evaluating 50 patients that utilized real-time ultrasound to perform closed pleural biopsies, the diagnostic yield was 94%.[97] In another study of patients with undiagnosed exudative pleural effusions, the use of ultrasound-guided thoracentesis and pleural biopsy had a combined diagnostic yield of 90% for malignancy.[98] CT is also a useful imaging modality to guide pleural procedures, with a reported sensitivity of 77% to 88% for diagnosis of malignant pleural disease.[95,96,99]

In summary, the use of image-guided closed pleural biopsy serves as an accessible, minimally invasive, and low-cost method to evaluate patients with undiagnosed exudative effusions, and may be particularly useful in patients with pleural abnormalities and in centers where medical thoracoscopy is not readily available.

Medical Thoracoscopy

Medical thoracoscopy, also known as pleuroscopy, is a minimally invasive procedure that involves accessing the pleural space with a rigid or semirigid thoracoscope that is typically performed with a local anesthetic and moderate sedation. The procedure enables the direct visualization of the parietal pleura in order to direct biopsies to visually abnormal areas. The sensitivity of medical thoracoscopy in diagnosing malignant pleural disease is approximately 90% to 95%,[99,100] and therapeutic pleurodesis or tunneled pleural catheter insertion can be performed during the same procedure. The diagnostic yield is similar to video-assisted thoracic surgery (VATS) pleural biopsy. However, medical thoracoscopy is associated with lower cost and shorter hospital length of stay, as the majority of cases can be performed in the outpatient setting.[101] Medical thoracoscopy is well tolerated and safe, with a mortality rate less than 0.5%.[100]

A recent study evaluating 1926 patients who underwent medical thoracoscopy showed that major complications, including lung laceration, major bleeding, prolonged air leak, and re-expansion pulmonary edema occurred in <1% of patients.[102] A CT scan of the chest, preferably with IV contrast, should be performed prior to the procedure to evaluate the size of the effusion, determine the presence of loculations, and assess for pleural abnormalities, such as pleural thickening, nodules, and masses. Contraindications to the procedure include lung adherent to the chest wall throughout the hemithorax, hypercarbia or severe respiratory distress, and uncontrollable cough. Optimal patient selection is best achieved through a multidisciplinary collaboration between interventional pulmonologists and thoracic surgeons.[100,103]

The field of medical thoracoscopy continues to evolve, and with advancements in thoracoscopic equipment and imaging technologies enabling smaller ports of entry and improved visualization of pleural abnormalities, the diagnostic and therapeutic indications for medical thoracoscopy are likely to continue to expand in the coming years.

Surgical Thoracoscopy

A surgical pleural biopsy is typically performed using VATS. Careful assessment of the patient's comorbidities and performance status should be performed to ensure that they can tolerate general anesthesia and single lung ventilation required for this procedure. Although VATS is still considered the gold standard for the diagnosis of malignant pleural disease, the diagnostic yield of >90% and complication rate of VATS is similar to medical thoracoscopy.[101] While evidence suggests that medical thoracoscopy is a less invasive and cost-effective alternative to VATS for the evaluation of an undiagnosed pleural effusion, approximately 12% of patients may still require a VATS or alternative surgical intervention following medical thoracoscopy for management of the pleural space.[103]

Although pleural fluid cytology, CT imaging of the chest, and thoracoscopy are diagnostic in the majority of cases, approximately 5% to 31% of patients with cytologically negative exudative effusions will remain undiagnosed following these procedures.[104] Thoracoscopic biopsies in these cases typically demonstrate nonspecific pleuritis that does not yield a specific etiology. While the majority of patients with nonspecific pleuritis are ultimately diagnosed with benign disease, approximately 14% will eventually be diagnosed with a malignancy, mostly mesothelioma.[104] As a result, these patients warrant close follow up for 1 to 2 years following thoracoscopy.

PROGNOSIS

The prognosis for patients with a malignant pleural effusion remains poor, with median survival estimates ranging from 3 to 12 months.[4] Survival is highly variable and depends on a number of factors including the primary tumor type, performance status, and pleural fluid markers. One of the most important determinants of survival is the primary tumor type. In a study evaluating prognostic estimates for malignant effusions across three international cohorts, the median overall survival for all patients was 4.5 months, with median survival estimates in lung cancer of 2.4 months, breast cancer 6.3 months, hematologic malignancies 7.2 months, and mesothelioma 11.2 months.[105]

The prognosis of the patients with a malignant pleural effusion may assist in guiding decisions regarding management options. For instance, in patients with very limited life expectancy, treatment may be focused on symptom relief and end-of-life care rather than definitive pleural intervention. As a result, a number of scoring systems have been developed to more accurately predict survival.

The LENT score is a prospectively validated scoring system to estimate survival in patients with a malignant effusion. The score includes the pleural fluid LDH, performance status, serum neutrophil-to-lymphocyte ratio, and primary tumor type, resulting in a composite score that separates patients into low-, moderate-, or high-risk groups, with median survival in these groups of 319, 130, and 44 days, respectively.[105] The accuracy and simplicity of this score makes it an attractive option for clinical use.

The more recently developed and validated PROMISE score combines well-known clinical prognostic factors with a novel pleural fluid biomarker, tissue inhibitor of metalloproteinases 1 (TIMP1), to predict 3-month mortality. By combining the prior receipt of chemotherapy, radiation therapy, performance status, primary tumor type, hemoglobin levels, white blood cell count, and C-reactive protein with measurement of TIMP1, patients are grouped into risk stratification categories ranging from category A ($<25\%$ absolute risk of death) to category D ($\geq 75\%$ absolute risk of death).[106] The majority of parameters within the PROMISE score are readily available in the clinical setting, and the score accurately estimates 3-month mortality; however, further external validation is needed before its routine use in clinical practice.

MANAGEMENT

The primary goal of treatment is palliation of symptoms related to the effusion and improvement in overall quality of life. Ideally, the therapy should minimize the need for hospitalization or medical visits while being affordable and safe. The preferred treatment option takes into consideration a patient's clinical condition and personal values to balance all competing factors.

Clinical observation may be offered for patients with small, asymptomatic, malignant pleural effusions. For patients with symptomatic effusions, management options include thoracenteses, drainage, and chemical pleurodesis via either chest tube thoracostomy or thoracoscopy/pleuroscopy, or the placement of an indwelling pleural catheter (IPC).

In patients with respiratory symptoms potentially attributable to a malignant pleural effusion, a therapeutic thoracentesis can be performed during the initial diagnostic evaluation. A thoracentesis enables the assessment of symptomatic relief following drainage, determination of whether the lung is nonexpandable following the procedure, and assessment of the rate at which fluid reaccumulates. Patients who derive symptomatic relief of dyspnea following thoracentesis should be considered for definitive pleural interventions (e.g., placement of a tunneled pleural catheter, pleurodesis), while those with persistent dyspnea despite effective fluid drainage should have further diagnostic testing to investigate alternative causes of dyspnea, such as lymphangitic carcinomatosis or a pulmonary embolism. Approximately 15% to 27% of patients may not appreciate significant improvements in dyspnea following therapeutic drainage. A thoracentesis can be performed quickly and safely both in the outpatient and inpatient settings. When performed by experienced operators, the respective risks of pneumothorax and bleeding are each less than 1%.[107] Traditional teaching recommends that drainage should be limited to 1 to 1.5 L to avoid the risk of re-expansion pulmonary edema.[48,108] However, evidence suggesting that the volume of fluid removed is not correlated with re-expansion pulmonary edema challenges this assertion.[109]

Thoracentesis is sufficient for many patients in controlling symptoms, especially amongst patients who are just beginning treatment with systemic therapies. If the rate of reaccumulation is sufficiently slow, serial thoracentesis can be performed. However, it is important to recognize that this therapeutic strategy is not appropriate for patients with rapidly recurring pleural effusions, as serial thoracenteses in this population have been associated with increased number of pleural procedures, complications, and emergency department visits.

For rapidly reaccumulating effusions, a more durable solution is recommended. One such option is pleurodesis, which involves generating inflammation within the thoracic cavity to promote adhesion of the visceral and parietal pleura. Successful pleurodesis obliterates the potential space for fluid reaccumulation, leading to sustained pleural effusion resolution. Pleurodesis is typically achieved chemically by the intrapleural instillation of a sclerosing agent. Many chemical sclerosants have been utilized to promote pleurodesis including talc, doxycycline, bleomycin, and povidone-iodine. Although there is no current consensus regarding the optimal chemical sclerosing agent, two recent studies suggest that the administration of talc is associated with fewer pleurodesis failures than other commonly used agents.[110,111] Talc has a pleurodesis success rate of approximately 70%[111] and can be delivered into the pleural space either as a slurry suspension via a chest tube or by direct aerosolized application (poudrage) via video thoracoscopy with similar efficacy.[111,112]

Small-bore intercostal catheters (10–14French) are similar in efficacy to large-bore intercostal tubes (24–32French) for pleurodesis but are associated with less pain.[113] Historically the median hospitalization time for a pleurodesis procedure is 7 days.[112] Pleurodesis is contraindicated in patients who cannot achieve apposition of the visceral and parietal pleura due to lack of lung expansion (Fig. 77-4).

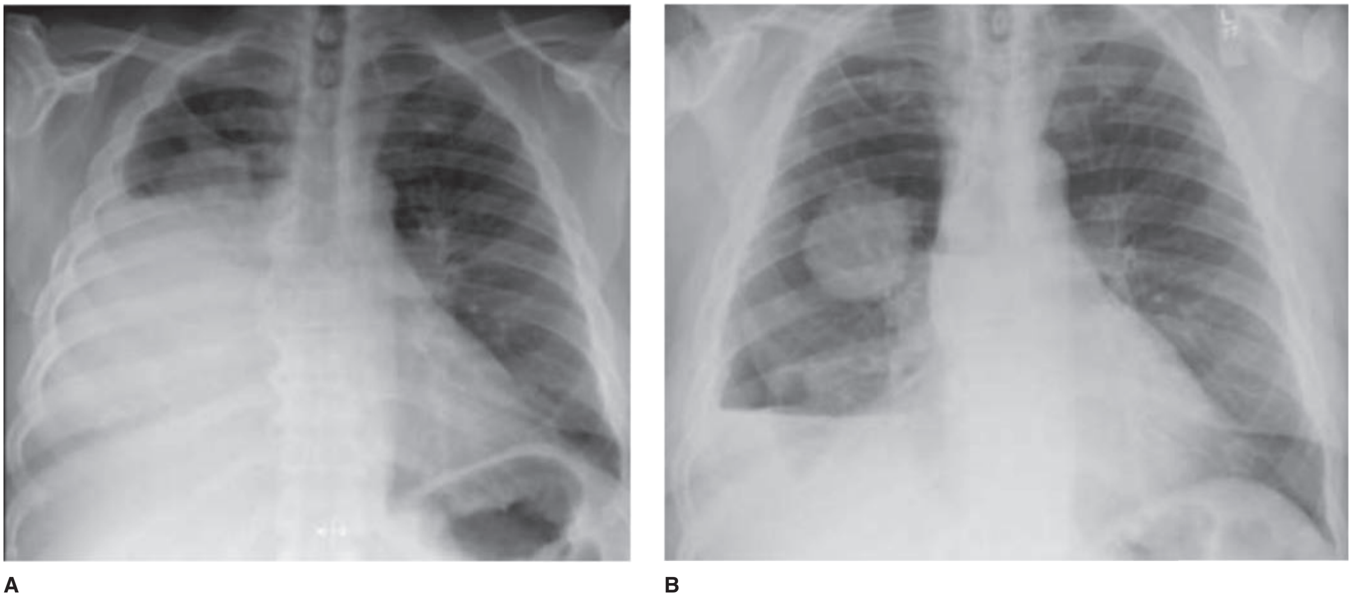

Figure 77-4 **A.** A chest radiograph of a patient presenting with shortness of breath found to have a large right pleural effusion. Cytologic evaluation of the right pleural fluid reveals metastatic lung adenocarcinoma. **B.** A chest radiograph in the same patient following a right thoracentesis showing a right upper lobe mass and lack of lung re-expansion. This patient would not be a candidate for pleurodesis due to the lack of lung re-expansion.

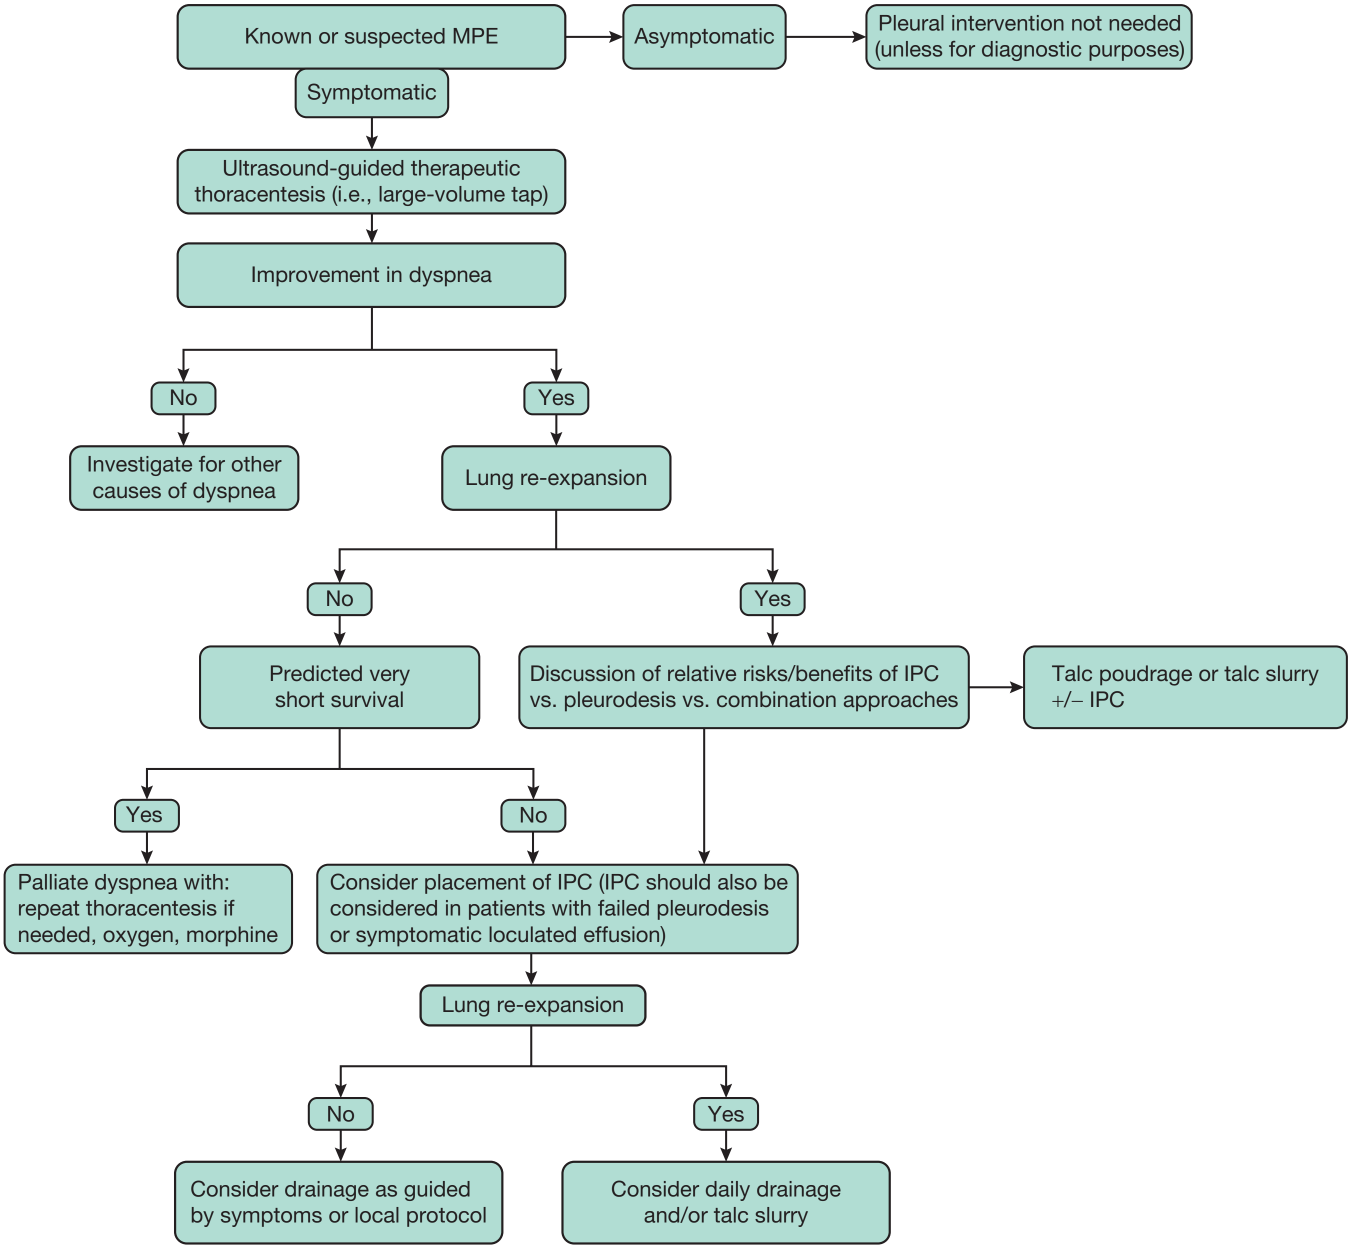
Fever and pain requiring oral or parenteral analgesics are the most common adverse events associated with chemical pleurodesis.[110] Postprocedural pain typically resolves within the first 24 h and can be mitigated by the intrapleural administration of a topical anesthetic prior to the instillation of the sclerosing agent. Previous reports of the development of the acute respiratory distress syndrome (ARDS) following talc pleurodesis were thought to occur as a consequence of nongraded/small-particle talc previously used in the United States; however, this risk appears minimal with modern talc preparations that include large-particle, graded talc.[114,115]

IPCs are an attractive alternative to pleurodesis. IPCs are fenestrated silicone catheters that are tunneled subcutaneously in the chest wall and subsequently inserted into the pleural space. They can be placed as an outpatient procedure, allowing immediate relief of symptoms without the need for hospitalization.[116–118] An IPC can be left in place indefinitely to allow regular drainage of the pleural space at home. Drainage can be performed by the patient, family members, or a visiting nurse. In patients with rapidly recurring malignant effusions without lung expansion, IPCs may be a more attractive solution than repeat thoracenteses. Compared to talc pleurodesis, IPC placement offers better control of dyspnea at 6 months, fewer days in the hospital, and less need for another pleural procedure such as thoracentesis or intercostal catheter placement. For these reasons, IPC placement is increasingly becoming the favored definitive approach to malignant pleural effusion management. The most common complications associated with IPCs include empyema, cellulitis, and catheter blockage.[119,120] These complications are usually minor and rarely necessitate removal of the catheter.

In 30% to 50% of patients with an IPC, sustained resolution of the effusion can be accomplished via a combination of response to



Known or suspected MPE
Asymptomatic
Pleural intervention not needed (unless for diagnostic purposes)
Symptomatic
Ultrasound-guided therapeutic thoracentesis (i.e., large-volume tap)
Improvement in dyspnea
No
Yes
Investigate for other causes of dyspnea
Lung re-expansion
No
Yes
Predicted very short survival
Discussion of relative risks/benefits of IPC vs. pleurodesis vs. combination approaches
Talc poudrage or talc slurry +/– IPC
Yes
No
Palliate dyspnea with: repeat thoracentesis if needed, oxygen, morphine
Consider placement of IPC (IPC should also be considered in patients with failed pleurodesis or symptomatic loculated effusion)
Lung re-expansion
No
Yes
Consider drainage as guided by symptoms or local protocol
Consider daily drainage and/or talc slurry

Figure 77-5 Suggested management pathway for malignant pleural effusion. *(Adapted with permission from Feller-Kopman DJ, Reddy CB, DeCamp MM, et al. Management of Malignant Pleural Effusions. An Official ATS/STS/STR Clinical Practice Guideline. Am J Respir Crit Care Med. 2018;198(7):839–849.)*

systemic treatment and the proinflammatory effects of the catheter itself. The median time to "autopleurodesis" in published series has been between 30 and 60 days.[116–118] Randomized, controlled trials comparing different drainage protocols have demonstrated higher autopleurodesis rates in association with more frequent drainage. In one study, every-other-day drainage was shown to have a pleurodesis rate of 24% at 90 days, compared with 47% in subjects who drained their catheter every day.[39] In another, similar trial, only 11% of subjects who drained their catheter on an as-needed basis achieved pleurodesis at 60 days, compared with 37% of subjects who drained their catheter daily.[121] Daily drainage demonstrated similar improvements in dyspnea compared with symptom-guided drainage and was not associated with more pain or pleural infections. Despite the improved rate of pleurodesis, a recent cost-effectiveness analysis showed that daily drainage was not a cost-effective alternative to symptom-guided drainage, as daily drainage demonstrated considerably higher costs compared with symptom-guided drainage.[122]

Recent studies have attempted to combine the benefits of chemical pleurodesis with the convenience of IPCs. In a randomized, placebo-controlled trial of patients with malignant effusions and expandable lung, chemical pleurodesis with talc slurry 10 days after IPC placement was associated with significantly higher pleurodesis rates at 35 days (43%) compared with IPC alone (23%).[123] This strategy was also associated with improved symptom and quality-of-life scores compared with IPC alone. Although the rate of successful pleurodesis was significantly lower than conventional chemical pleurodesis through a chest tube, this strategy offers the convenience of avoiding the time and cost of a hospitalization and is a promising approach for patients without nonexpandable lung. A trial studying the efficacy of this combined procedure compared with VATS pleurodesis is currently ongoing (ClinicalTrials.gov identifier NCT04322136).

Significant advancements have been made in the management of malignant pleural effusions over the last 20 years. The recent American Thoracic Society/Society of Thoracic Surgeons/Society of Thoracic Radiology Clinical Practice Guidelines on the Management of Malignant Pleural Effusions synthesize the latest body of evidence and provide a suggested management pathway for malignant pleural effusions (Fig. 77-5).[47]

Ongoing work continues to explore the optimal combination of treatment strategies that maximize quality of life while minimizing cost and risk to the patient. Improvements in understanding the underlying pathophysiology may ultimately enable the development of intrapleural targeted therapies that control pleural fluid formation to optimize patient care and minimize the need for symptomatic drainages.

CHAPTER 78

Malignant Mesothelioma and Other Primary Pleural Tumors

Daniel H. Sterman
Edmund K. Moon
Keshav Mangalick
Leslie A. Litzky

INTRODUCTION

The pleura is a membranous structure covering the entire surface of the lung and lining the inside of the chest cavity. It is composed of a thin mesothelial layer with underlying fibroblasts and varying amounts of collagenous fibrous tissue with interdigitating capillaries and venules. The most common tumors of the pleura are metastatic neoplasms, predominantly of lung, breast, or colonic origin. Tumors arising primarily from the pleura are rare but still constitute a variety of benign and malignant lesions from several different cells of origin, some of which have yet to be identified.

MALIGNANT MESOTHELIOMA

The most common primary malignant tumor of the pleura is malignant mesothelioma, an insidious neoplasm with a generally dismal prognosis arising from the mesothelial surfaces of the pleural and peritoneal cavities, as well as from the tunica vaginalis and pericardium. Eighty percent of all cases of mesothelioma are pleural in origin.

■ Epidemiology

The incidence of mesothelioma in the United States is estimated to be 3300 cases per year.[1] The incidence within the United States peaked in the year 2000 and is now declining, secondary to control of asbestos exposure.[2] However, incidence is increasing in other parts of the world, such as Europe, Japan, and Australia. Deaths from mesothelioma in Great Britain continued to increase and peaked at an annual average of 2540 deaths per year between 2012 and 2018 before decreasing to 2369 in 2019. However, this trend was largely driven by a peak and decrease in deaths among males, and it is unclear when female deaths will peak (https://www.hse.gov.uk/statistics/causdis/mesothelioma/mesothelioma.pdf).[3] Subsequent mesothelioma rates were expected to drop in England and other developed countries because of legislation aimed at reducing asbestos exposure in the workplace and the general environment. In contrast, mesothelioma incidence rates are predicted to escalate for much longer times in developing countries because of poor regulation of asbestos mining and widespread industrial and household utilization of asbestos.[3–5]

■ Etiology

Inhalational exposure to asbestos has been clearly established as the predominant cause of malignant mesothelioma in humans. Approximately 70% of cases of pleural mesothelioma are associated with documented asbestos exposure. In ancient Greece, the philosopher Pliny first established the association between asbestos exposure and lung disease by making the observation that slaves working in asbestos mines were less healthy than other slaves. It was not until 1960, with the publication by Wagner et al.[6] of a series of 33 mesothelioma cases occurring in a crocidolite mining community in South Africa, that the etiologic connection between asbestos and mesothelioma was established. Wagner's study was soon followed by several other accounts of mesothelioma afflicting asbestos workers at locations around the world. In addition to asbestos miners and workers, other occupations at especially high risk include plumbers/pipefitters, mechanical engineers, and ship and boat building and repairing.[4]

The lifetime risk of developing mesothelioma among asbestos workers is thought to be as high as 8% to 13%.[7] There is a latency period of approximately 30 to 40 years from the time of initial asbestos exposure to the development of mesothelioma. It remains unclear whether there is a dose–response relationship between asbestos exposure and development of mesothelioma. The possibility of a dose–response relationship was demonstrated in a cohort study of more than 4500 people who resided in an Australian city that produced crocidolite asbestos but who did not directly participate in its mining or milling. In this study, the incidence of mesothelioma increased significantly with greater environmental exposure, based upon the neighborhood and duration of residence. In a cohort of textile workers with heavy exposure to asbestos, the risk of pleural mesothelioma was increased and was proportional to the latency period. In contrast, many well-documented cases of mesothelioma occur after brief, but intense, or longer-term low-level exposures to asbestos (e.g., spouses of asbestos workers exposed by washing clothes).[8]

Asbestos is not a specific compound, but the commercial name for a group of hydrated magnesium silicate fibrous minerals divided into two major types: the serpentines and the amphiboles. Serpentine chrysotile fibers, which account for more than 95% of the asbestos previously used for industrial purposes in the United States, are spiral-shaped, pliable, easily breakable, and soluble in tissues, whereas the amphiboles (crocidolite, amosite, tremolite, anthophyllite, actinolite) are rigid, long, and needle-like, with a longer biologic persistence than the serpentine fibers. The carcinogenicity of asbestos is thought to depend on dose, biodurability, surface reactivity, and the physical properties of the fibers. Fibers with a high length-to-width ratio, such as crocidolite, which are able to more readily penetrate through the lung to the pleural surface, are considered more carcinogenic. Among the remaining asbestos fibers, amosite has an intermediate carcinogenic risk, chrysotile the lowest. It is unclear whether the cases of mesothelioma attributed to chrysotile exposure are caused primarily by the chrysotile itself or by contamination with tremolite fibers. All asbestos fiber types, however, have carcinogenic potential.[3,4]

The development of malignant pleural mesothelioma has also been associated in rare cases with other etiologic factors, including therapeutic ionizing irradiation to supradiaphragmatic fields,[9–13] intrapleural thorium dioxide (Thorotrast), and inhalation of other fibrous silicates such as erionite. Epidemiologic studies of a region in central Anatolia (Turkey) with an abnormally high incidence of pleural mesothelioma (22 per 10,000 individuals >25 years old) implicated routine household use of a locally ubiquitous silicate, erionite, as a potential etiologic agent. However, it appears that only specific families (who appear to have as yet to be fully defined genetic abnormalities) are susceptible to erionite-induced mesothelioma.[14]

■ Molecular Pathogenesis

The latency period from asbestos exposure to the development of mesothelioma ranges from approximately 20 to 50 years, suggesting the necessity of multiple genetic alterations for eventual malignant transformation of the mesothelium. Despite extensive investigation, the exact mechanisms of asbestos carcinogenesis have not yet been fully elucidated. In rodent model systems, asbestos fibers act like tumor promoters in combination with a carcinogen, eliciting proliferation of mesothelial cells. Asbestos fibers can also interact with the mitotic spindle to cause missegregation of chromosomes and aneuploidy. In rat pleural mesothelial cells, asbestos fibers and erionite have been shown to induce the proto-oncogenes c-fos and c-jun in a prolonged and dose-responsive manner. Several growth factors, secreted by mesothelial/mesothelioma cells in an autocrine fashion, have been implicated in various stages of mesothelioma tumorigenesis. Platelet-derived growth factors A and B (PDGF A and B), insulin-like growth factors 1 and 2 (IGF-1 and IGF-2), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), hepatocyte growth factor, and transforming growth factor β1, β2, and β3 (TGF-β1, -β2, and -β3) constitute a complex mixture of autocrine and paracrine stimuli for mesothelioma cell proliferation as well as initiation of tumor angiogenesis. More recently, asbestos has been shown to induce necrotic cell death with resultant release of high-mobility group protein B1 (HMGB-1) in the extracellular space, which leads to a chronic inflammatory response involving macrophage accumulation and secretion of tumor necrosis factor α (TNF-α). This in turn activates NF-κB, leading to survival of human primary mesothelial cells that have accumulated genetic damage from asbestos exposure. There is also evidence implicating aberrant activation of the Wnt signaling pathway in mesothelioma.[15,16]

It has been well established that chronic inflammation predisposes to cancer development. Asbestos fibers appear to stimulate the production of chronic oxidative stress in lung macrophages and other cells for many years. In animal models, crocidolite fibers clearly induce specific DNA adducts (8-hydroxydeoxyguanosine, 8-OHdG) associated with oxidative damage in the DNA from peritoneal cells and macrophages of asbestos-exposed animals. These same types of 8-OHdG DNA adducts have been observed in the blood lymphocytes of asbestos-exposed individuals decades after exposure, suggesting chronic exposure to oxidant stress.[17]

The pathogenesis of malignant mesothelioma involves molecular changes such as chromosomal alterations in tumor suppressor genes, allele loss, gene silencing by DNA methylation in specific chromosomal regions, epigenetic dysregulation of tumor suppressor genes by histone acetyltransferase and histone deacetylase (HDAC), chromatin condensation/decondensation balance, and gene mutations. Analysis of explanted human mesotheliomas and cultured human mesothelioma cell lines has revealed a number of cytogenetic aberrations that may predispose to the development of the malignant phenotype. Partial or total loss of chromosomes 1, 3, and 4, deletions of 9p, and monosomy of chromosome 22 are the most common abnormalities seen. For mesotheliomas, 9p deletions have been associated with the loss of function of the p16INK4 cdk inhibitor, a putative tumor suppressor gene, engendering unchecked cdk4-mediated phosphorylation of the retinoblastoma 1 (Rb1) gene product and leading to loss of regulation of cell division. Monosomy 22, the most frequent numeric cytogenetic abnormality in mesothelioma, has recently been correlated with mutations in the neurofibromatosis 2 (NF2) tumor suppressor gene mutations more commonly associated with acoustic neuromas, schwannomas, and meningiomas. The product of NF2, Merlin, appears to inhibit cell proliferation and cell cycle progression by repressing cyclin D1 expression as well as inhibiting invasiveness. The presence of the Wilms tumor suppresser gene (WT1) in human mesotheliomas raises the possibility that alterations in this gene or binding of the WT1 gene product to the p53 tumor suppressor may predispose to mesothelial cell carcinogenesis.[15,16,18]

Viral Oncogenes

Simian virus 40 (SV-40) is a polyoma virus with oncogenic potential in humans. Its actions are thought to result from inactivation of tumor suppressor genes such as the retinoblastoma gene (Rb) and wild-type p53 (wt p53) by a peptide known as the SV-40 large T antigen (Tag). SV-40 is a potent oncogenic virus in human and rodent cells; SV-40 DNA sequences have been identified in brain tumors, osteosarcomas, and lymphomas.[19] SV-40 is the only agent known to cause malignant transformation of human primary mesothelial cells in vitro.[20] When cell lines are exposed to both SV-40 and asbestos fibers, the rate of transformation increases significantly. Animal studies have also shown that crocidolite asbestos and SV-40 can act as cocarcinogens.[21] Several studies have documented the presence of SV-40 in patients with mesothelioma (some of whom did not have obvious asbestos exposure), as well as in cases of atypical mesothelial proliferation.[22–26] As an example, one report examined 35 archival mesothelioma specimens and found that SV-40–like sequences were present in 86% of cases.[23] However, the possibility that technical factors can produce false-positive results suggestive of SV-40 infection also has been raised.[27,28] Despite the fact that there was worldwide dissemination of SV-40–contaminated polio vaccines in the 1950s and 1960s, there is no convincing epidemiologic evidence linking SV-40 exposure to the development of malignant mesothelioma.

Nonetheless, it is possible that Tag interference with Rb and wt p53 may play an accessory role in the carcinogenesis of malignant mesothelioma.[29] If this hypothesis is validated, novel strategies of vaccination to prevent mesothelioma or molecular techniques to improve early diagnosis may become possible.

Genetic Predisposition

Gene polymorphism studies are in their early stages in asbestos-exposed populations. Some suggestive associations in DNA repair genes with mesothelioma development have been reported but need validation. One study reported an increased incidence of mesothelioma among asbestos-exposed individuals in Finland found to be lacking the glutathione-S-transferase M1 (GSTM1) gene and carrying the "slow-acetylator" type of the *N*-acetyltransferase 2 (NAT-2) gene.[30] The GSTM1 gene is important in the detoxification of several carcinogens, including polycyclic aromatic hydrocarbons; NAT-2 is associated with the biotransformation of aromatic amines. Some genetically predisposed families have been identified, but without identification of a specific "mesothelioma" gene. An increased frequency of polymorphisms in the NOD-like receptor pyrin domain (NLRP) inflammasome complex among a cohort of Italians with mesothelioma also has been described.[31] Inactivation of the nuclear deubiquitinase BAP1, which appears to regulate key histones and transcription factors related to the development of tumors, is associated with malignant pleural mesothelioma.[32] A so-called BAP1 "syndrome" has been described in some families bearing this gene mutation, in which there is higher frequency of mesothelioma, ocular melanoma, and melanocytic lesions of the skin, sometimes even occurring simultaneously in the same individual.[33]

Pathology

Gross and microscopic pathologic findings in malignant mesothelioma are discussed below.

Gross Pathology

The vast majority of malignant mesotheliomas involving the pleura are those tumors that diffusely involve the pleura and are properly termed *diffuse pleural mesothelioma*. A rare localized gross variant of malignant mesothelioma that forms a single mass arising in the pleura but is otherwise microscopically identical to diffuse malignant mesothelioma has been described and termed *localized pleural mesothelioma*. Diffuse malignant mesothelioma begins as multiple discrete nodules that, in earlier stages, tend to preferentially involve the parietal pleura over the visceral pleura. In time, these nodules tend to coalesce on the visceral and parietal pleural surfaces with subsequent fusion of the pleurae. Progressive tumor growth typically leads to partial or complete encasement of the lung with rinds of pleural tumor that can be several centimeters in thickness but may show only minimal penetration of the underlying lung parenchyma (Fig. 78-1). Advanced cases show more extensive spread along interlobar fissures, deeper invasion into the underlying lung parenchyma and through the diaphragm, and contiguous involvement of the chest wall, pericardium, and mediastinum. Although it is rare for patients with mesothelioma to present clinically with metastatic disease, peribronchial lymphovascular spread, regional lymph node metastases, and extrathoracic hematogenous metastases become increasingly common over the course of the disease. Seventy percent of patients have mediastinal lymph node involvement at autopsy. Hematogenous metastases follow the exact same pattern of spread as non–small-cell lung carcinomas with involvement of the contralateral lung and pleura, liver, adrenals, bone, brain, and kidney.

Histology

The 2021 revision of the WHO classification of pleural tumors recognizes three major histologic subtypes: epithelioid, sarcomatoid, and biphasic.[34] The desmoplastic variant is considered a subtype of sarcomatoid mesothelioma. The entity formerly termed *well-differentiated papillary mesothelioma* has been removed from the mesothelioma grouping and is now its own separate entity. This particular entity has been renamed *well-differentiated papillary mesothelial tumor* and is restricted to an exceptionally rare and distinctive mesothelial tumor that is composed of papillary stromal formations covered by cytologically bland mesothelial cells lacking invasion.[34] Part of the practical diagnostic utility of the WHO classification is that each mesothelioma subtype is associated with a particular differential diagnosis that guides the pathology workup. This workup requires additional time and expense because of the ancillary studies that are required for definitive diagnosis. From a prognostic perspective, studies have shown that the pure epithelioid subtype has a difference in survival in many instances and hence may affect therapy selection. It should also be recognized that the larger the tissue sample, the more frequent the histologic variation and the higher the incidence of biphasic tumors.[35]

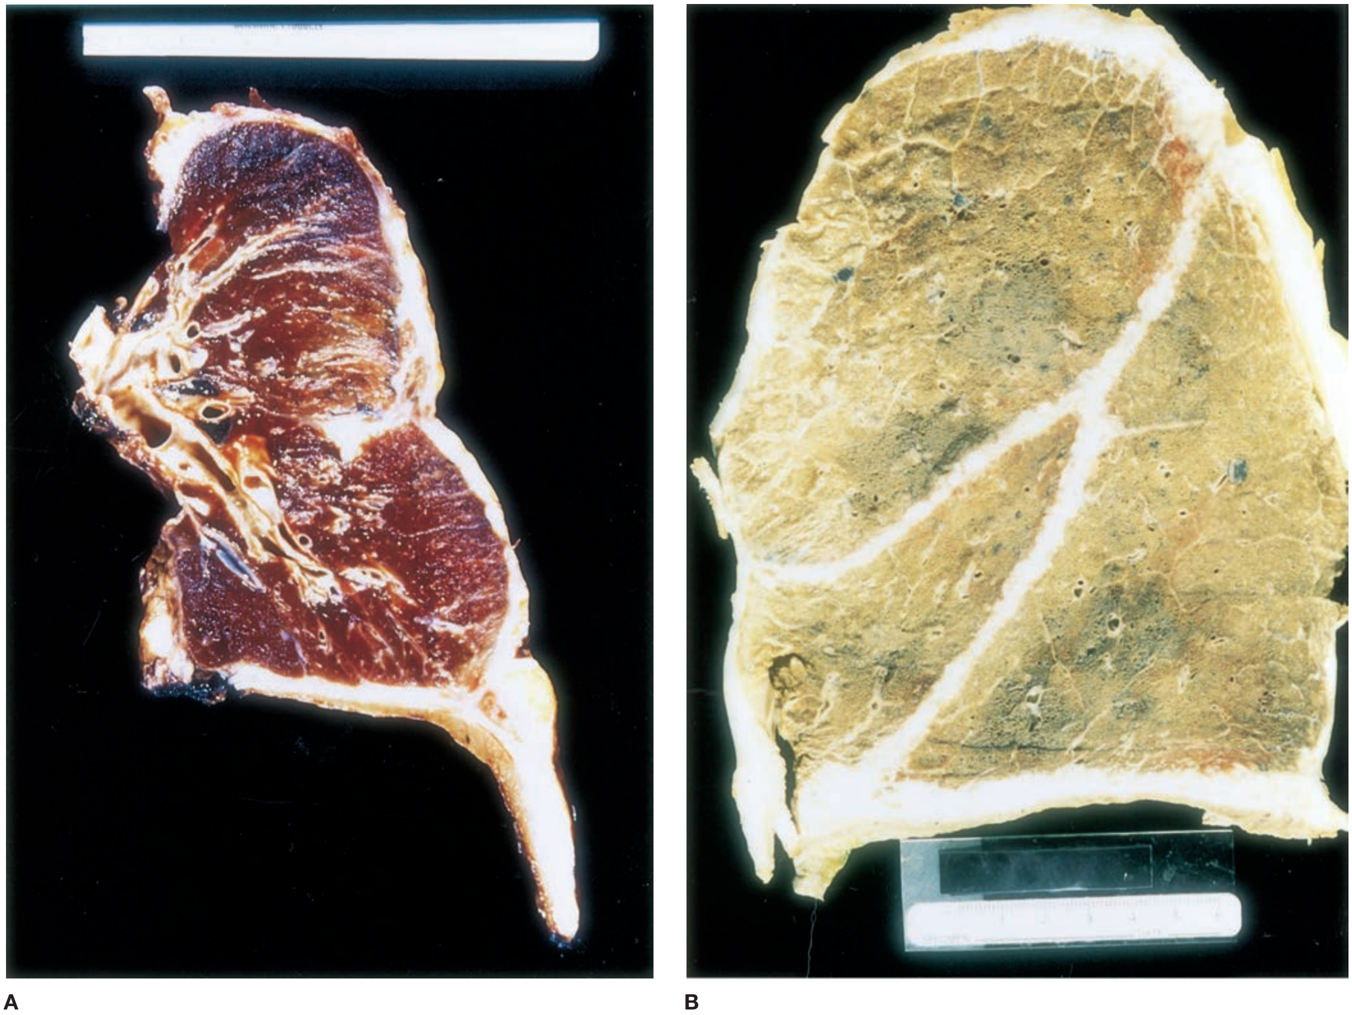

Figure 78-1 **A.** Transverse section of an extrapleural pneumonectomy surgical specimen with the entire right lung, parietal and visceral pleurae, portions of pericardium, and the majority of the right hemidiaphragm. Note the thick rind of tumor along the pleural surface encasing the lung and invading the diaphragm. **B.** Postmortem mesothelioma specimen with overnight formalin inflation and fixation. The right lung pictured is covered by a thick, whitish rind of tumor involving the entire pleural surface, which has also infiltrated and demarcated the interlobar fissures.

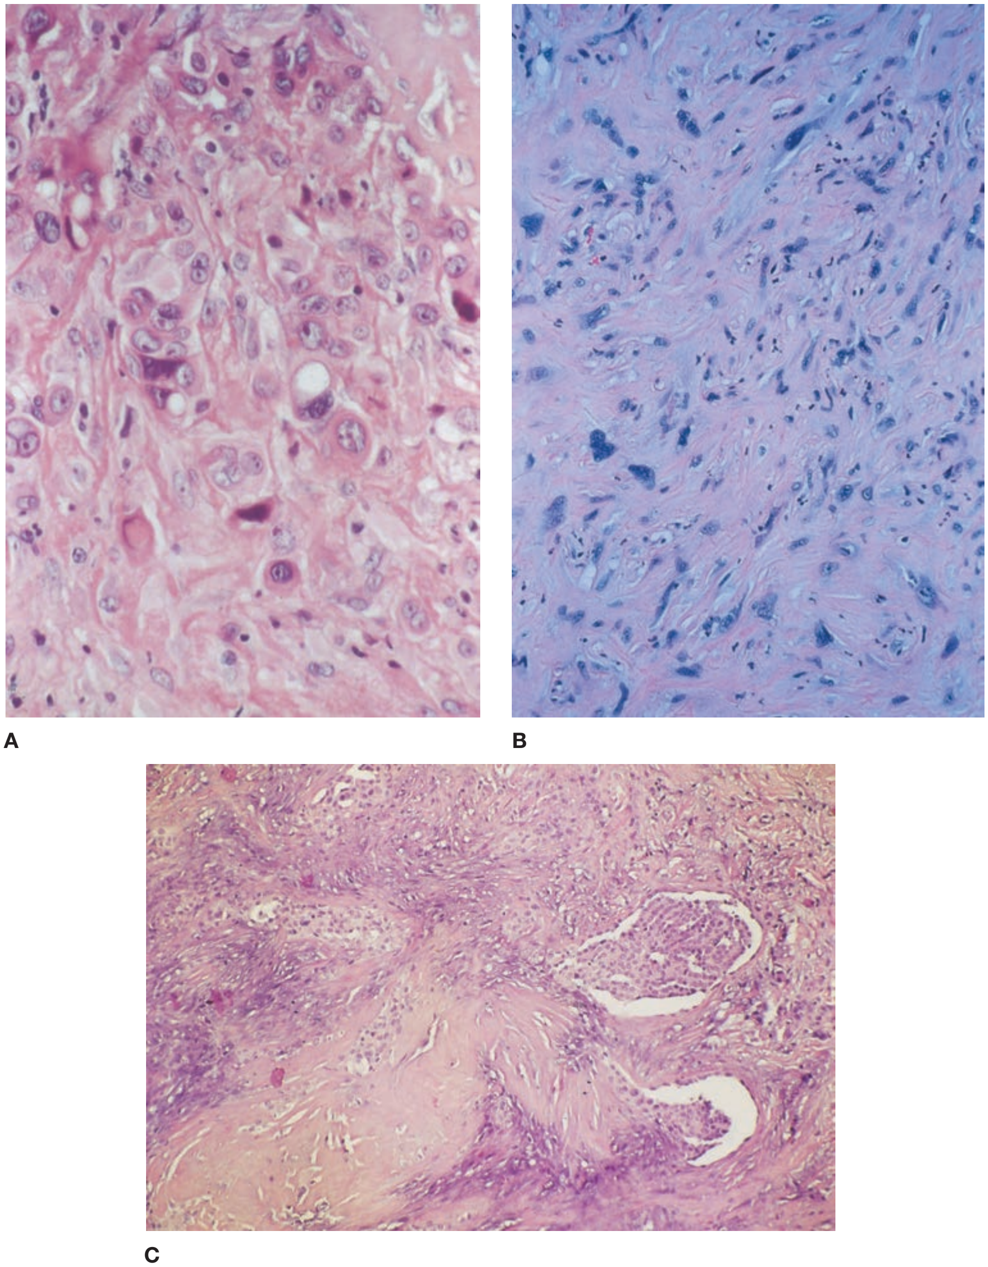

Figure 78-2 **A.** Photomicrograph of an epithelial malignant mesothelioma. These sheets of pleomorphic cells are epithelial in appearance, with eosinophilic cytoplasm and fairly well-defined cell borders. Note the cytoplasmic vacuoles, which can lead to confusion with a signet ring type of adenocarcinoma. By electron microscopy, these vacuoles can be shown to contain crystallized hyaluronic acid (H&E, ×400). **B.** Photomicrograph of a sarcomatoid malignant mesothelioma. This tumor has a malignant mesenchymal appearance with bizarre, spindled cells and a growth pattern resembling that of a sarcoma. These cells demonstrated strong cytokeratin positivity on immunohistochemical staining, distinguishing this tumor from a sarcoma (H&E, ×400). **C.** Photomicrograph of a biphasic malignant mesothelioma. This tumor demonstrates several areas of epithelioid histology with a papillary growth pattern seen against a background of spindled and more poorly differentiated epithelioid cells (H&E, ×200).

The epithelioid subtype is the most common, with a wide range and mix of histologic patterns. Common histologic variants of this subtype include tubulopapillary, trabecular, micropapillary, and solid (Fig. 78-2A). Less common variants include adenomatoid, rhabdoid, deciduoid, small cell, and signet ring patterns. A myxoid matrix may be prominent and may be mistaken for mucin, but this matrix is actually hyaluronate and shows hyaluronidase-sensitive staining with Alcian blue. There are data to support the utility of nuclear grading of pleural diffuse epithelioid mesothelioma. The proposed grading system is based on a score for nuclear atypia and mitotic count, as well as the presence or absence of necrosis.[34] Although grading of epithelioid mesothelioma had not been widely performed prior to the 2021 WHO classification, it is now recommended in both biopsy and resection specimens to help in the recognition of tumors that may behave in a more aggressive fashion. Pleomorphic features—specifically prominent anaplastic/bizarre nuclei and multinucleated giant cells—can be seen in the epithelioid type and should be reported as another indicator of aggressive behavior. Lymphohistiocytoid features—characterized by dense lymphoid infiltrates composed mainly of CD8+ T cells that obscure the malignant histiocytoid appearing tumor cells—similarly should be reported. Both pleomorphic and lymphohistiocytoid features can be seen in biphasic or sarcomatoid subtypes and should be recorded as well.

Sarcomatoid mesotheliomas can also have a wide variety of histologic patterns. The most frequently encountered pattern is that of fibroblastic-like spindle cells arranged in storiform, fascicular, or haphazard patterns that mimic a fibrosarcoma (Fig. 78-2B). Some sarcomatoid mesotheliomas have "heterologous elements" such as rhabdomyosarcoma, osteosarcoma, and chondrosarcoma. Benign osteoclast-like giant cells also may be seen, as well as the previously mentioned pleomorphic or lymphohistiocytoid features. Transitional features have been described as elongated but plump tumor cells, intermediate in morphology between the epithelioid and sarcomatoid subtypes. The transitional tumor cells are more round than sarcomatoid tumor cells but more discohesive than epithelioid tumor cells. A reticulin stain will highlight single tumor cells. The survival data to date appear to support grouping these tumors with transitional features with sarcomatoid mesothelioma.

Desmoplastic mesotheliomas, by definition, have areas of densely collagenized tissue with atypical cells arranged in a storiform or "patternless" pattern. This pattern should constitute at least 50% of the tumor in resection specimens. The deceptively bland appearance of the tumor makes its separation from fibrous pleuritis exceedingly difficult, particularly with limited sampling. Studies that have examined the criteria used for diagnosis have highlighted the importance of "interface biopsies" in which unequivocal evidence of invasion into the underlying adipose tissue, skeletal muscle, or lung may be demonstrated. Other criteria, which may require multiple tissue sections to detect, include obvious sarcomatoid areas, foci of necrosis, and distant metastases. Bone metastases similarly may be deceptively bland and confused with a primary benign fibrous tumor of bone.

Biphasic mesotheliomas have both epithelioid and sarcomatoid components (Fig. 78-2C). Each component should represent at least 10% of the tumor for the designation of biphasic mesothelioma in resected specimens. However, a tumor can be designated as biphasic regardless of the percentage of each component in a small biopsy sample. Whether in a small biopsy specimen or larger resection, the percentage of the sarcomatoid component should be noted because of the potential impact on treatment options and prognosis. Biphasic mesotheliomas represent about 30% of cases. As previously noted, the percentage of biphasic tumors increases with larger tumor samples.

Immunohistochemistry

Immunohistochemistry (IHC) has replaced electron microscopy as the gold standard for diagnosis. This is because of the comparative low cost, ease, and greater availability of IHC, as well as the expanded array of commercially available antibodies that are reliable markers of mesothelial differentiation. Because there is no single marker with sufficiently high sensitivity and specificity for malignant mesothelioma, it is standard practice for pathologists to employ a panel of markers (both positive and negative) to confirm the diagnosis of malignant mesothelioma. Guidelines for the pathologic diagnosis of malignant mesothelioma were first published in 2009 in a consensus statement from the International Mesothelioma Interest Group and are periodically updated.[36] As in any instance in which IHC is used as an adjunct in tumor diagnosis, careful consideration must be given to the tumor's histologic appearance as well as the clinical-radiographic context and the differential diagnosis that is generated from this information.

Broad-spectrum cytokeratin (CK) antibody cocktails are essential in the diagnosis of malignant mesothelioma. In epithelioid tumors, strong and diffuse CK positivity can be used to exclude the rare case of large cell lymphoma, epithelioid vascular tumors, or melanoma involving the pleura. CK reactivity usually differentiates malignant mesotheliomas from many sarcomas, although there are occasional CK-negative sarcomatoid mesotheliomas as well as focally CK-positive sarcomas. Although CK positivity does not distinguish malignant mesothelioma from reactive lesions, positive CK staining may help to highlight invasion into adjacent structures.

Common affirmative immunohistochemical markers, which, if positive, can be used to support a diagnosis of malignant mesothelioma include calretinin, CK5/6, the Wilms tumor 1 (WT1) antigen, and D2-40 (Fig. 78-3).[36] These markers are most useful in the narrow differential diagnosis of malignant epithelioid mesothelioma versus primary pulmonary adenocarcinoma. It should be noted that these markers do not invariably exclude other tumors, including metastases from nonpulmonary primary sites. A wide variety of markers can be used to support a diagnosis of adenocarcinoma, as opposed to malignant mesothelioma. Markers such as MOC31, CEA, Ber-EP4, thyroid transcription factor 1 (TTF-1), and napsin A are commonly included in such panels.[36] The sensitivity and specificity of both the affirmative mesothelioma markers as well as the adenocarcinoma markers vary greatly when the differential diagnosis is broadened to include other subtypes of primary pulmonary carcinoma such as squamous cell carcinoma or metastases from extrapulmonary sites such as the kidney and ovary. Both categories of markers are generally less reliable with focal to absent staining in the differential diagnosis of sarcomatoid lesions. The immunohistochemical panel that is recommended for the initial evaluation of a sarcomatoid tumor involving the pleura includes CKs (including AE1/3, CAM5.2, CK18, and CK7), calretinin, and D2-40.[36] If other types of sarcomas are being considered, then the marker panel should be expanded accordingly to include antibodies such as CD31, CD34, desmin, myoglobin, and S-100. The guidelines previously mentioned include a number of specifically recommended panels to assist pathologists in the selection of markers according to the differential diagnosis and the need to exclude other primary sites.

IHC has also been utilized to increase our understanding of the interface between tumors and surrounding/infiltrating immune cells, otherwise known as the tumor microenvironment (TME). Marcq et al. analyzed the TME of samples from patients with malignant mesothelioma, some of whom had been previously treated with chemotherapy, and others who were treatment-naïve. In their study population, PD-1 and CD45RO expression in the tumor stroma was associated with worse response to chemotherapy, whereas PD-1, CD4, AND TIM3 expression in lymphoid aggregates was associated with improved clinical prognosis. Interestingly, the investigators were able to confirm qualitative visual evidence of tumor-infiltrating lymphocytes in their samples, and in the previously treated samples there was no tumoral expression of PD-1 or PD-L1, possibly providing mechanistic support for the combination of chemotherapy and immunotherapy.[37] A study by Uijie et al. specifically examined markers on tumor infiltrating immune cells from 230 patients with malignant mesothelioma and compared their IHC findings with clinical data, noting that higher infiltration of CD163+ macrophages and CD8+ T cells was associated with improved survival, whereas decreased infiltration of CD163+ macrophages and higher levels of CD20+ T cells were both associated with poorer survival.[38]

■ Other Ancillary Studies

Histochemical stains for the presence of intracytoplasmic mucin are still occasionally used as a means of differentiating adenocarcinomas from epithelioid malignant mesotheliomas. Mucicarmine and periodic acid–Schiff (PAS) with diastase are the two most frequently used. These stains are technically easy to perform, inexpensive, and rapid. Care must be taken to exclude the possibility of false-positive staining that can be seen with hyaluronate. The use of histochemical

Only minimal background staining is present.

staining (Alcian blue with hyaluronidase) to detect the high levels of hyaluronic acid in mesothelioma cells was used far more frequently before the widespread use of IHC.

Electron microscopy had traditionally been considered the gold standard for the diagnosis of malignant mesothelioma and ultrastructural analysis.[39] The predominant epithelioid form is composed of polygonal cells with numerous long surface microvilli, prominent desmosomes, and abundant tonofilaments (Fig. 78-4). Electron microscopy of the sarcomatoid variant reveals the presence of elongated nuclei, CK and vimentin filaments, copious rough endoplasmic reticulum, some intracellular attachments, and rare microvilli. Electron microscopic studies may be inconclusive in poorly differentiated tumors of either subtype and have no utility in the diagnosis of desmoplastic malignant mesothelioma. Molecular analysis can be performed on formalin-fixed, paraffin-embedded tissue to demonstrate the X:18 translocation characteristic of synovial sarcoma—a biphasic or monophasic sarcomatoid tumor that can involve the pleura. As discussed at the end of the chapter, synovial sarcoma should be considered in the differential diagnosis of a pleural tumor with a biphasic or monophasic spindle cell appearance.

■ Molecular Profiling

Compared with routine histologic evaluation and classification, the examination of multiple expressed genes and/or proteins within individual tumors may be more informative for making diagnoses, estimating prognosis, and anticipating response to therapy. The development of microarray methodology, which permits the expression of thousands of genes to be assayed simultaneously, represents a powerful technique to read the "molecular signature" of an individual patient's tumor, a process termed *gene expression profiling*. Gene expression profiling studies have been used to identify genes with potential pathogenic significance, such as aurora kinases or key inhibitors of apoptosis proteins. Profiles have also been identified that help to reliably differentiate different subtypes of mesothelioma. By using gene expression ratios, it is possible to reliably distinguish between epithelioid mesothelioma and lung adenocarcinoma or ovarian carcinomas from peritoneal mesotheliomas.[40,41] An area of active investigation is the use of expression profiles as a means of predicting outcome and clustering groups of patients with pleural mesothelioma into those with good-risk disease (i.e., more likely to be cured using aggressive therapy) and poor-risk disease (i.e., with a low cure rate despite aggressive therapy). Some groups have found this approach to be highly predictive, whereas others suggest the accuracy has been overestimated.[42]

Over the past several years, as the ability to sequence genomes and characterize and quantify gene expression has improved, more has been discovered about the molecular profile of malignant mesothelioma. A large genomic analysis of tumors from patients with MPM by Bueno et al. found a heavy burden of mutations in the genes *BAP1*, *NF2*, *TP53*, *DDX3X*, *SETD2*, *SF3B1*, and *TRAF7*. However, the tumor samples had a relatively low level of mutations that caused alterations in the resultant proteins. In addition, distinct

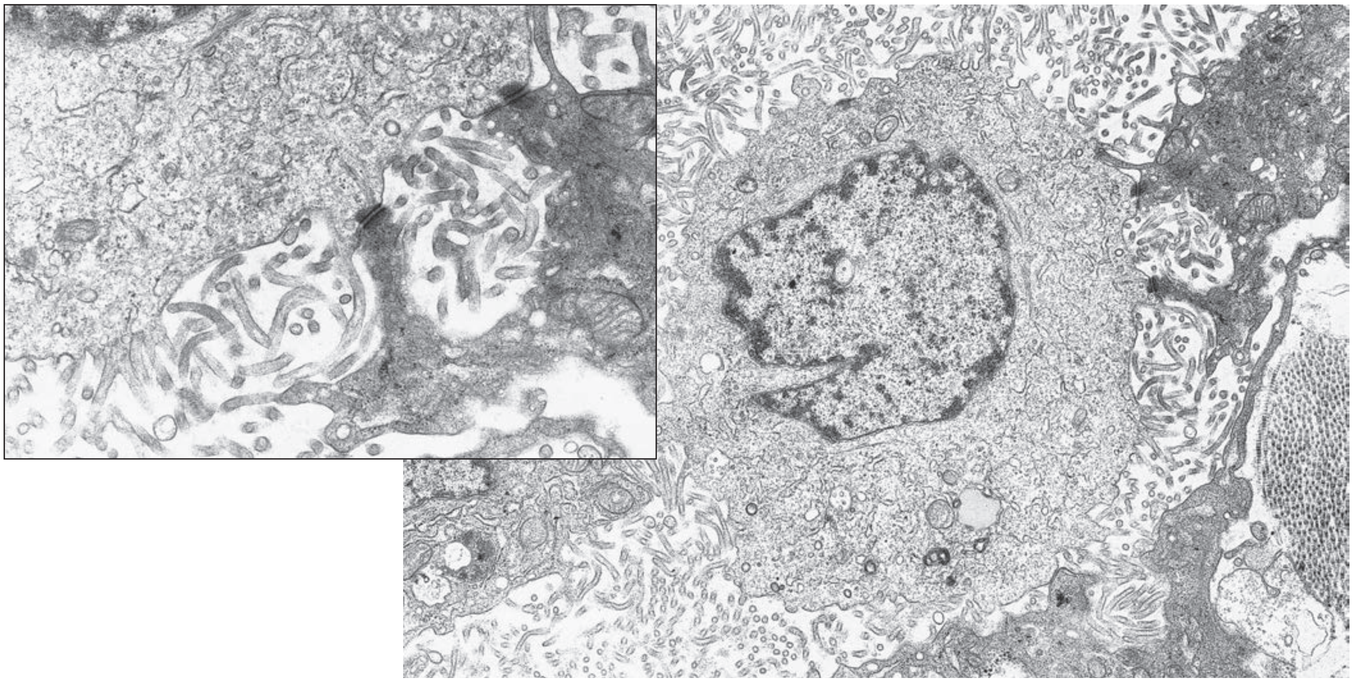

Figure 78-4 Electron micrograph of a human mesothelioma cell showing abundant microvilli arising from the cell surface and prominent desmosomes (×10,500; inset, ×30,000). *(Reproduced with permission from Dr. Giuseppe G. Pietra, Department of Pathology and Laboratory Medicine, University of Pennsylvania Medical Center, Philadelphia.)*

mutational profiles for sarcomatoid and epithelioid histologies were determined, with biphasic tumors more closely resembling a sarcomatoid profile.[43]

Clinical Presentation

Malignant mesothelioma most commonly presents in the fifth to seventh decades of life. Most patients diagnosed with mesothelioma earlier in life have a history of childhood asbestos exposure. The most frequent presenting symptoms of pleural mesothelioma, which are caused by the presence of extensive intrathoracic disease, are nonpleuritic chest pain (60%–70% of patients), dyspnea (25%), and cough (20%). Some patients are asymptomatic at diagnosis, with unilateral pleural effusions found incidentally on routine chest radiographs. Mesothelioma is typically a unilateral disease—only 10% of patients with mesothelioma have bilateral involvement at presentation. In more advanced stages of disease, physical findings may include unilateral dullness to percussion and decreased air movement throughout the hemithorax, asymmetric chest wall expansion during respiration, palpable chest wall masses, and scoliosis toward the side of the malignancy.

Radiographic Presentation

The most common initial radiographic manifestation of pleural mesothelioma is a large unilateral pleural effusion, often with contralateral mediastinal shift (Fig. 78-5A). Sixty percent of patients have right-sided lesions, putatively related to the gravitational predilection for inhaled asbestos fibers and dusts to travel directly to the right lower lobe airways. Occasionally, mesothelioma can present as unilateral, concentric, plaque-like, or nodular pleural thickening, but effusions may obscure the presence of the underlying pleural thickening. The tumor frequently extends into the fissures, which become thickened and irregular in contour. Only 20% of patients with pleural mesothelioma have radiographic signs of asbestosis (i.e., bibasilar interstitial fibrosis), although many have evidence of pleural plaques and/or calcifications. In later stages of disease, ipsilateral mediastinal shift is seen secondary to encasement of the lung by a thick rind of tumor and resultant significant unilateral loss of lung volume. Patients with advanced mesothelioma may also have other radiographic signs of volume loss—diaphragm elevation and intercostal space narrowing. They may also have mediastinal widening owing to direct tumor invasion or lymph node involvement, enlargement of the cardiac margins secondary to pericardial invasion with effusion, and evidence of rib destruction or soft tissue masses extending from the chest wall.[44] Chest computed tomography (CT) is important in detecting invasion of chest wall, ribs, and mediastinal structures, as well as extension along the pleural surfaces and diaphragm (Fig. 78-5B). Furthermore, CT scans can distinguish between pleural thickening and effusion.[45] Coronal magnetic resonance imaging (MRI) is helpful in discerning the extent of disease, particularly invasion of the chest wall, endothoracic fascial involvement, and extension of pleural mesothelioma through the diaphragm into the peritoneal cavity.[46] In one study of 95 patients with pleural mesothelioma, MRI was directly compared with CT scan. The overall diagnostic accuracy for mediastinal nodal disease was approximately 50% for both modalities, but MRI outperformed CT for detection of diaphragmatic invasion (82% vs. 55% accuracy, respectively), and for detecting invasion of endothoracic fascia or chest wall (69% vs. 46%, respectively).[47]

Positron Emission Tomography

The role of positron emission tomography (PET) imaging, particularly PET/CT, in the care of patients with mesothelioma is multifold. It can be used in diagnosis and staging by evaluating the extent of pleural disease, establishing mediastinal lymph node involvement, evaluating tumor invasion into the lung and thoracic wall, and detecting extrathoracic metastases. It is becoming particularly useful to assess the treatment response to chemotherapy and radiotherapy and also plays an important role in the planning of radiation therapy.

The role of PET scans with 18-fluorodeoxyglucose (FDG) in staging and preoperative evaluation is evolving. In a small study of

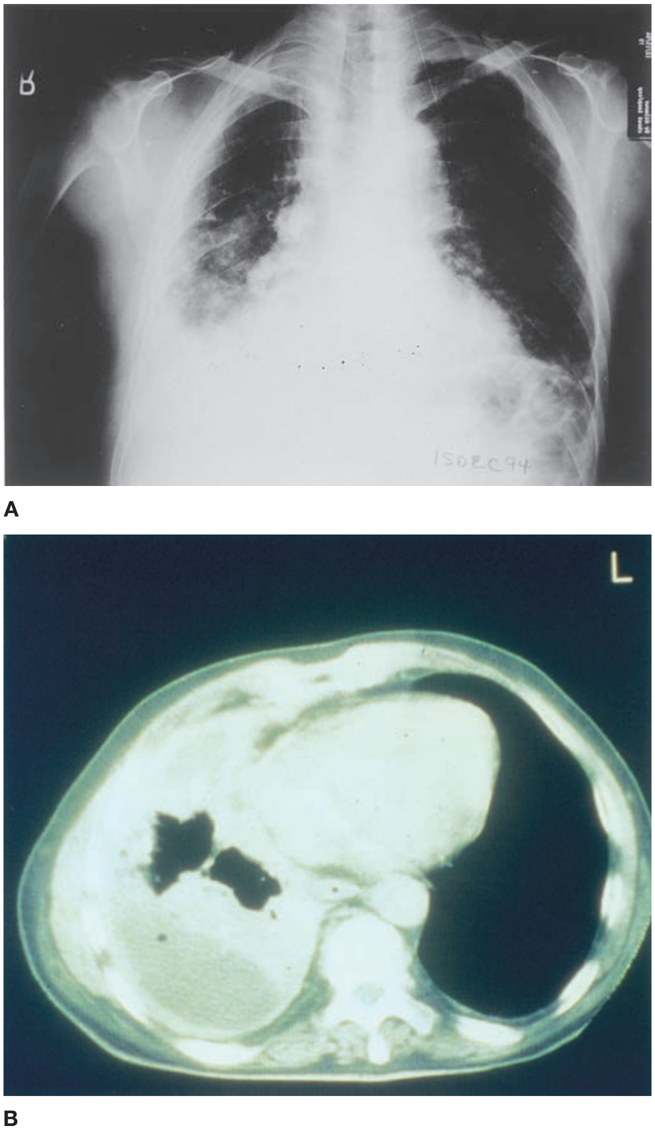

Figure 78-5 **A.** Posteroanterior chest radiograph in a patient with malignant pleural mesothelioma demonstrating significant right-sided pleural effusion and diffuse pleural thickening associated with marked volume loss of the right hemithorax. No definite calcified pleural plaques are seen. **B.** Computed axial tomographic image from a patient with pleural mesothelioma, illustrating complete encasement of the ipsilateral lung with a thick rind of tumor, neoplastic invasion of the interlobar fissures, small residual pleural effusion, and marked unilateral volume loss.

28 patients with suspected pleural mesothelioma who underwent 18-FDG PET scanning followed by thoracoscopic or open surgical biopsy, PET was shown to be better than CT for differentiating malignant from benign pleural processes. Uptake of FDG was significantly higher in malignant lesions, and an overall sensitivity and specificity of 91% and 100% could be achieved with PET scanning for the detection of malignant compared with benign disease. However, hypermetabolic lymph nodes were detected in 12 patients (of whom 9 had a normal CT scan), and only 5 had histologically proven malignant nodal disease.[48]

In another small study, PET assessment demonstrated pleural lesions in 12 of 13 patients with malignant pleural disease (malignant pleural mesothelioma in 10 patients, adenocarcinoma in 2 and liposarcoma in 1), also revealing distant metastases in 2 patients. A patient with an epithelial mesothelioma had a false-negative result. In a study of 16 patients with pleural changes, PET correctly identified all 12 malignant cases; conversely, the 4 patients who had no FDG uptake all had benign pleural disease (fibroma, tuberculous pleurisy, empyema, and pleural fibrosis).[49]

PET scan appears more sensitive than CT for finding extrathoracic disease, but it has limited sensitivity for locoregional staging (i.e., determining potential resectability). In a retrospective study, 60 patients with malignant pleural mesothelioma were identified who had undergone PET scans preoperatively and the results of clinical staging were compared with surgical and pathologic results. FDG uptake was detected in 59, and the 1 false-negative case had disease limited to the parietal pleura (stage IA). The sensitivity of PET scans for determining the presence of T4 (unresectable) disease was only 19% (7 of 21 patients). Among the 31 patients whose nodal status was assessed pathologically, only 1 of 9 patients with N2 disease was correctly identified by PET scan, and the overall sensitivity for nodal disease was only 11%.[50]

PET scanning may help differentiate between benign and malignant pathology when patients present with a chest radiograph demonstrating pleural abnormalities. One study demonstrated that dual timepoint FDG PET scanning, which measures uptake of ^{18}F-FDG over time, could distinguish between benign and malignant pleural diseases among 55 suspected cases.[51]

One of the potential future uses of PET that needs to be further evaluated is its utilization in the screening of patients with a history of significant asbestos exposure. These patients may potentially harbor microscopic disease, not apparent on CT or MRI, which may be amenable to early aggressive therapy. Because of the limits of detection of current ^{18}F-FDG PET technology, the use of PET for screening for pleural mesothelioma must await the development of novel radiopharmaceuticals.

PET scans can also be used to predict survival and response to therapy. One study involving 177 patients with mesothelioma found that patients with tumors demonstrating intense FDG avidity (standardized uptake value >5) had a far worse prognosis. Another study showed that decreased radiopharmaceutical uptake on follow-up PET scans performed early after treatment may be an excellent predictor of overall clinical response.[52] Furthermore, there is evidence supporting the use of PET scans after neoadjuvant chemotherapy to determine those who will benefit most from moving on to surgical resection.[53]

Laboratory Studies

Although there are no specific pleural fluid biomarkers for malignant mesothelioma, evaluation of pleural fluid chemistries may still be beneficial. Effusions associated with mesothelioma are strongly exudative, with elevated protein concentrations in the range of 4 to 5 g/dL and a lymphocytic predominance. Pleural fluid lactate dehydrogenase (LDH) concentrations often exceed those of patients with carcinomatous pleural effusions, with levels greater than 600 IU/L. In patients with advanced disease and extensive involvement of visceral and parietal pleura, pleural fluid pH and glucose are commonly low. In patients with mesothelioma, the presence of a low pleural fluid pH denotes both a poor overall prognosis and refractoriness to achieving successful palliative pleurodesis. In addition, the pleural effusion associated with mesothelioma is characteristically highly viscous, presumably because of elevated concentrations of hyaluronic acid.[54] An increased pleural fluid hyaluronidase level is suggestive but not diagnostic of mesothelioma.[55] The cytokine profile of pleural effusions related to mesothelioma is somewhat unique in that the tumor constitutively produces high concentrations of interleukin 6 (IL-6) and transforming growth factor-β (TGF-β), but relatively low levels of IL-1β and TNF-α. These elevated intrapleural levels of IL-6 in patients with malignant mesothelioma are postulated to induce systemic manifestations such as fever, cachexia, and thrombocytosis.[56,57]

Pulmonary function testing typically demonstrates a restrictive pattern resulting from pleural effusions, tumor encasement of the lung, or chest wall involvement.

Mesothelin and Other Novel Serum Markers

There is increasing evidence supporting the clinical utility of a monoclonal antibody–based serum assay for a soluble form of the protein mesothelin (soluble mesothelin–related peptide [SMRP]). Mesothelin is a 40-kDa glycoprotein that is found in low levels on the cell surface of normal mesothelial cells (lining the pleura, peritoneum, pericardium, and tunica vaginalis), but is highly expressed on mesothelioma, pancreatic cancer, and ovarian cancer cells.[58,59] Multiple studies have observed that SMRP can be elevated in serum and pleural fluid of patients with mesothelioma.[60] Increased levels of SMRP were found in serum samples from 37 of 44 patients with mesothelioma (87%), compared with 3 of 160 patients with other cancers or inflammatory lung or pleural diseases (2%), and none of 28 controls without a past asbestos exposure.[61] At the present time, SMRP levels play an adjunctive role in the diagnosis of patients with mesothelioma. A meta-analysis of 16 diagnostic studies found that the sensitivity ranged widely from 19% to 68%, depending on the specific criterion for positivity.[60] SMRP has also been measured in pleural fluid. In a retrospective study of 192 patients with pleural effusion (52 patients with malignant mesothelioma, 56 with nonmesotheliomatous malignancies, and 84 with nonneoplastic effusions), the assay had a sensitivity of 67% with a specificity of 98%.[62] It is intriguing to posit that SMRP may also play a role in screening of high-risk patients for incipient mesothelioma. In one report, 7 of 40 asbestos-exposed individuals had elevated levels and 4 of these 7 subsequently developed mesothelioma or lung cancer within 1 to 5 years.[61] However, measurement of SMRP is indicated currently only for monitoring patients in whom the diagnosis has already been established.

Osteopontin, a glycoprotein that mediates cell–matrix interactions and is overexpressed in several types of cancer, was higher in patients with malignant mesothelioma than in patients with asbestos-related nonmalignant pleural disease or no prior asbestos exposure in a study of 190 patients.[63]

Fibulin-3 is an extracellular glycoprotein that is encoded by the epidermal growth factor–containing fibulin-like extracellular matrix protein 1 (EFEMP1) gene. Initial studies found that elevated levels of fibulin-3 in the plasma had high sensitivity and specificity (97% and 96%, respectively) in distinguishing patients with pleural mesothelioma from those with a history of asbestos exposure but without mesothelioma and from those with other malignancies or benign causes of pleural effusion. Levels of fibulin-3 decreased in patients with mesothelioma who underwent surgical resection. Additional studies will be required to determine its role as a biomarker for early diagnosis and monitoring of patients who have undergone therapy.[64]

Diagnosis

The differential diagnosis of malignant pleural mesothelioma includes both benign and malignant processes. Inflammatory reactions such as chronic, organized empyema can mimic the dense pleural thickening and large, viscous pleural effusions characteristic of mesothelioma. As discussed, epithelial mesotheliomas can be extremely difficult to distinguish grossly and histologically from metastatic adenocarcinoma to the pleura from any number of primary sources, including lung, breast, stomach, kidney, ovary, and prostate. Sarcomas such as fibrosarcoma can present in similar fashion to sarcomatoid mesotheliomas. The mixed-cellular (biphasic) subtype of mesothelioma can bear a significant histologic resemblance to sarcomatoid carcinomas and synovial sarcoma.

Thoracentesis or closed pleural biopsy can often establish the diagnosis of pleural malignancy but may not provide enough diagnostic material to determine the specific diagnosis of mesothelioma. Immunohistochemical markers and monoclonal antibodies may aid in differentiating mesothelioma from other carcinomas on cytology specimens. In addition, certain cytopathologic features of cells obtained from pleural fluid have been found to correlate well with the presence of mesothelioma, including papillary aggregates, multinucleation with atypia, cell-to-cell apposition, nuclear pleomorphism, and macronucleoli. Gene expression ratios also may be increasingly helpful in this regard. Negative results from thoracentesis and/or pleural biopsy do not exclude the diagnosis of mesothelioma, and therefore surgical biopsy, which has a higher diagnostic yield, should be pursued in patients with high clinical suspicion.

Surgical intervention, via video-assisted thoracoscopic surgery (VATS) or open thoracotomy, is often necessary to firmly establish the diagnosis. Boutin et al. from Marseille prospectively evaluated VATS for the diagnosis of malignant pleural mesothelioma in 188 consecutive patients from 1973 to 1990 and found that thoracoscopic biopsy was diagnostic in 98% of cases, compared with only 26% for thoracentesis alone, and 39% for fluid cytology and closed pleural biopsy. These thoracoscopic procedures were performed under local anesthesia in an endoscopy suite with minimal morbidity or complications.[65] It is important to note that approximately 10% of patients who undergo a transthoracic diagnostic procedure for mesothelioma may seed the biopsy site with tumor cells, later developing chest wall recurrences. This complication can potentially be prevented by prophylactic radiation therapy to the surgical incision or thoracentesis sites (Fig. 78-6).

Concurrent bronchoscopy may be important in distinguishing between mesothelioma and metastatic adenocarcinoma of the lung, as endobronchial lesions are rarely seen in mesothelioma. In addition, both endobronchial ultrasound–guided transbronchial needle aspiration (EBUS-TBNA) and mediastinoscopy play important roles in the diagnosis and staging of mesothelioma, as several studies have documented the significant negative prognostic implications of mediastinal nodal invasion in this disease. In comparative trials, EBUS-TBNA may actually have a higher sensitivity and specificity for determining mediastinal nodal involvement than mediastinoscopy.[66,67]

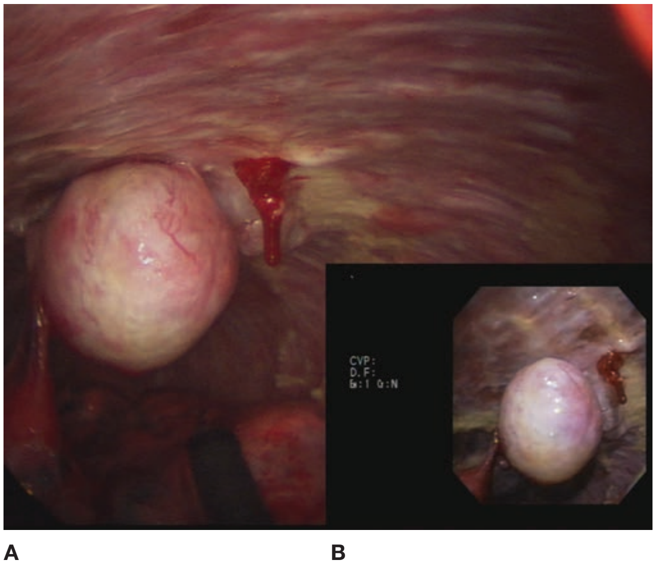

Figure 78-6 **A.** View of a mesothelioma tumor in the pleural cavity attached to the visceral pleura through surgical thoracoscope. **B.** View of the same tumor through a flexible medical pleuroscope.

TABLE 78-1 Butchart Staging System

Stage I	Tumor confined within the "capsule" of the parietal pleura
Stage II	Tumor invading chest wall or involving mediastinal structures
Stage III	Tumor penetrating diaphragm to involve peritoneum; involvement of opposite pleura; lymph node involvement outside the chest
Stage IV	Distant blood-borne metastases

Staging

The staging of malignant mesothelioma has proved to be more controversial than that of many other tumors. The most commonly used schema was devised by Butchart in 1976 (Table 78-1). Although useful, its ability to predict survival is weakened by lack of inclusion of lymph node involvement and chest wall invasion. For this reason, the Union Internationale Contre le Cancer (UICC) in 1990 first proposed a staging system based on the TNM (tumor, node, metastasis) standard used for many other tumors. In the TNM staging system, stages I and II disease have pleural involvement, potentially including diaphragmatic muscle or pulmonary parenchyma, but no evidence of lymph node involvement, distant metastases, or locally advanced, unresectable disease. Stage III mesothelioma includes those cases with regional lymph node involvement. Stage IV includes those with locally advanced and unresectable disease, contralateral lymph node involvement, supraclavicular lymph node involvement, and/or distant metastases.[68] More recently, Rusch et al. from the International Mesothelioma Interest Group (IMIG) proposed an updated staging system based upon tumor descriptors, providing precise anatomic definitions of the local extent of the primary tumor. This staging system (Table 78-2) was designed to provide the framework for proper analysis of prospective clinical trials of new treatment modalities.[69]

Clinical Course and Complications

The morbidity and mortality associated with mesothelioma are chiefly related to inexorable local invasion. Patients typically develop dyspnea and chest pain as tumor and fibrosis gradually obliterate the pleural space and replace any pleural fluid. As the tumor spreads, it covers both visceral and parietal pleural surfaces, encasing the ipsilateral lung with a thick, fibrous peel that extends into interlobar fissures and occasionally into lung parenchyma. Deoxygenated blood is shunted through the trapped lung, leading to significant dyspnea and to hypoxemia that is often refractory to supplemental oxygen. Dyspnea also results from abnormal chest wall mechanics secondary to tumor invasion into ribs as well as intercostal nerves and muscles. Local invasion of crucial thoracic structures can result in dysphagia, hoarseness, cord compression, brachial plexopathy, paralysis, Horner syndrome, and superior vena cava syndrome. Hilar and mediastinal lymph node involvement occurs at diagnosis in fewer than 50% of patients but is a harbinger of poor prognosis. Transdiaphragmatic spread into the abdominal cavity rapidly leads to intraperitoneal dissemination, with encasement of the mesentery and small and large bowel. Local invasion into the pericardial space can lead to pericardial effusion and tamponade. Distant metastatic disease by hematogenous spread is unusual early in the course of mesothelioma but may present in liver, bone, brain, adrenals, thyroid, and kidney. Widespread metastatic disease is more often a manifestation of end-stage malignant mesothelioma.[5,70–73]

TABLE 78-2 International Mesothelioma Interest Group (IMIG) Staging System

T1	T1a: Tumor limited to ipsilateral parietal pleura T1b: Tumor involving ipsilateral parietal pleura, with scattered foci of tumor on visceral pleural surface
T2	Tumor involving all ipsilateral pleural surfaces with diaphragmatic invasion or extension into underlying pulmonary parenchyma
T3	Involvement of the endothoracic fascia; mediastinal fat; solitary, resectable chest wall focus; or nontransmural pericardial invasion
T4	Diffuse extension into chest wall, peritoneum, spine, mediastinal organs, contralateral pleura, internal surface of pericardium or myocardium
NO	No regional lymph nodes metastases
N1	Metastases in the ipsilateral bronchopulmonary or hilar lymph nodes
N2	Metastases in the subcarinal or ipsilateral mediastinal lymph nodes
N3	Metastases in the contralateral mediastinal or internal mammary lymph nodes or any supraclavicular node metastasis
Staging	
Stage I	Ia: T1aN0M0 Ib: T1bN0M0
Stage II	T2N0M0
Stage III	Any T3M0, any N1M0, any N2M0
Stage IV	Any T4, any N3, any M1

Mortality

Median survival of patients with mesothelioma is between 8 and 14 months and varies depending on stage, histologic subtype, and concomitant medical problems. Patients with pleural mesothelioma most commonly die from local extension and respiratory failure, primarily related to spread to the contralateral hemithorax. As mentioned, tumor extension below the diaphragm may result in death from small bowel obstruction. Patients may also die from arrhythmias, heart failure, or stroke caused by tumor invasion of the heart or pericardium.[5,70–73]

Paraneoplastic Syndromes

Disseminated intravascular coagulation, migratory thrombophlebitis, thrombocytosis, Coombs-positive hemolytic anemia, hypoglycemia, and hypercalcemia associated with secretion of a parathyroid hormone–like peptide have all been described in the setting of mesothelioma.[73]

Prognostic Factors

Poor prognosis at the time of presentation is indicated by the presence of thrombocytosis, leukocytosis, low hemoglobin, fever of unknown origin, sarcomatoid or mixed histology, age greater than 65 to 75 years, poor performance status, and male sex. Good prognosis at presentation is associated with epithelioid histology; percentage of epithelioid histology; stage I disease; age under 65 years; Eastern Cooperative Oncology Group (ECOG) performance status of 0 to 1; absence of chest pain; and the presence of symptoms for more than 6 months prior to diagnosis.[74–78] Based on data from the most recent Surveillance, Epidemiology, and End Results (SEER) study of patients with mesothelioma, those who were female, were younger, received surgery with or without radiation, and had early-stage disease tended to have longer survival.[79] Patients with mesothelioma who are considered for surgery tend to be a highly selective group with highly localized disease and excellent performance status, corroborating these findings. However, the association of female sex with increased survival does not have a clear etiology, and it may be prudent for future clinical trials in mesothelioma to control for the percentage of female subjects enrolled when calculating mortality data.

The prognostic scoring systems derived by the Cancer and Leukemia Group B (CALGB) and the European Organization for Research and Treatment of Cancer (EORTC) are the most useful clinical prognostic scoring schemes available. They incorporate both the extent of disease and systemic factors. The CALGB evaluated the impact of clinical characteristics on the survival of 337 patients treated with chemotherapy for advanced mesothelioma in sequential phase II treatment studies over a 10-year period. In multivariate analysis, serum LDH greater than 500 IU/L, poor performance status, chest pain, platelet count greater than 400,000/μL, nonepithelial histology, and age older than 75 years jointly predicted poor survival. Six distinct prognostic subgroups were generated with median survival times ranging from 1.4 to 13.9 months. The median survival overall was 7 months. This prognostic schema was subsequently validated in an American phase II trial evaluating the investigational agent ranpirnase, and in an independent European data set.[77]

The EORTC prognostic scoring system was derived from an analysis of data from 204 adults who were entered into 5 consecutive phase 2 trials over 9 years. When 5 factors were taken into consideration (poor performance status, high WBC count, male sex, sarcomatoid cell type, and the certainty of the diagnosis), favorable and poor prognostic groups could be delineated, with 1-year survival rates of 40% and 12%, respectively. Median survival from the date of study entry was 8.4 months.[80,81] The relevance of these earlier prognostic indicators is somewhat limited given that the study was performed in the pre-pemetrexed era. However, the prognostic significance of the EORTC index has subsequently been confirmed in a multivariate analysis of a phase 3 trial assessing cisplatin plus raltitrexed.

■ Current Approaches to the Treatment of Pleural Mesothelioma

Over the past several years, advances have been made that have improved our ability to treat malignant pleural mesothelioma and, possibly, the quality and quantity of life for patients with mesothelioma. Extensive investigation has demonstrated significantly increased efficacy of combination immunotherapy as a new frontline therapeutic option for a subset of patients with mesothelioma, adding to the existing multimodality treatment programs that combine surgical cytoreduction with novel forms of radiation therapy and chemotherapy regimens. Innovative palliative approaches have proved successful in alleviation of the symptoms experienced by many mesothelioma patients. Continued investigation of immunotherapy and gene therapy present a window of hope for all mesothelioma patients to obtain significantly increased survival and quality of life.

Chemotherapy

Over the past 20 years, several phase 2 single-agent and combination chemotherapy studies have been performed in mesothelioma. These studies have demonstrated evidence of antitumor activity with anthracyclines, platinum derivatives, and antimetabolites. Combination chemotherapy has been associated with higher overall response rates but not, until recently, longer median survivals.[82]

The current standard of care for first-line chemotherapy in good performance status patients with unresectable mesothelioma is combination treatment with cisplatin and pemetrexed. Pemetrexed is an antifolate compound that targets multiple enzymes in the folate metabolism pathway. Pemetrexed is a potent inhibitor of thymidylate synthase, the rate-limiting step in the synthesis of thymidylate, which is required for DNA synthesis. Thymidylate synthase is also the enzyme inhibited by the cytotoxic agents 5-fluorouracil and raltitrexed.

In 2003, Vogelzang et al. reported the results of a phase 3 randomized clinical trial in chemotherapy-naïve mesothelioma patients comparing treatment containing pemetrexed and cisplatin with cisplatin monotherapy. A total of 456 patients were randomized: 226 received pemetrexed and cisplatin, 222 received cisplatin alone, and 8 never received therapy. Median survival time in the combination pemetrexed/cisplatin arm was 12.1 months versus 9.3 months in the cisplatin-only arm ($p = 0.\ 02$). The hazard ratio for death of patients in the combination arm versus those in the control arm was 0.77. Median time to progression was significantly longer in the pemetrexed/cisplatin arm: 5.7 months versus 3.9 months ($p = 0.\ 001$). Response rates were 41.3% in the pemetrexed/cisplatin arm versus 16.7% in the control arm ($p < 0.0001$). The addition of folic acid and vitamin B_{12} to chemotherapy resulted in reduction in the severity and frequency of hematologic and nonhematologic toxicities in the pemetrexed/cisplatin arm.[83] Another randomized phase 3 study of cisplatin with a newer-generation antifolate, raltitrexed showed similar increases in survival.[84] Pemetrexed plus carboplatin may be an alternative regimen if cisplatin toxicity is a particular concern, particularly in elderly patients or those with compromised renal function.[85]

For over a decade, the standard of care for first-line chemotherapy for unresectable mesothelioma was combination therapy with cisplatin and pemetrexed.[83] In 2016, the Mesothelioma Avastin Cisplatin Pemetrexed Study (MAPS) trial was the first trial to demonstrate the efficacy of antiangiogenesis in the treatment of mesothelioma. Patients who received bevacizumab in combination with standard chemotherapy demonstrated significantly longer survival than those receiving pemetrexed and a platinum agent alone (overall survival 18.8 months vs. 16.1 months). However, the addition of bevacizumab was also associated with an increase in adverse events (71% vs. 62%), particularly vascular adverse events—a substantial consideration in a disease that primarily affects older adults.[86]

The combination of gemcitabine and cisplatin or carboplatin is also a valid first-line option in the treatment of mesothelioma owing to its acceptable toxicity profile, good response rate, and palliative effects. A Northern Italian phase 2 study of gemcitabine and carboplatin in patients with pleural mesothelioma reported a 26% partial response rate and a median response duration of 55 weeks. There were also significant palliative benefits: decreased dyspnea in 46% of patients, weight gain in 40%, and pain reduction in 26%. Median survival for patients in this study was 66 weeks.[87] The potential value of the gemcitabine plus cisplatin regimen was also demonstrated in a second multicenter phase 2 trial, in which 106 previously untreated patients were treated with gemcitabine plus cisplatin and randomly assigned to receive either bevacizumab or placebo. The median survival was approximately 15 months in both treatment arms, consistent with the results seen with cisplatin plus pemetrexed. The trial showed no benefit from the addition of bevacizumab to the regimen.[88] An ongoing randomized clinical trial in Europe is evaluating the benefit of bevacizumab in combination with standard first-line pemetrexed-based chemotherapy.

There is no current standard of care for second-line chemotherapy in mesothelioma following treatment with cisplatin and pemetrexed. The most commonly used second-line regimens include gemcitabine or other drugs with single-agent activity such as vinorelbine. A large, double-blind, randomized clinical trial of the HDAC inhibitor vorinostat in second-line therapy for mesothelioma showed no survival benefit for study drug over placebo.[89] There exists insufficient evidence to recommend second-line chemotherapy as a standard treatment. Patients with adequate performance status should be enrolled onto clinical trials of second-line experimental therapies.

Radiation Therapy

Contrary to the prevailing wisdom that malignant pleural mesothelioma is a radioresistant neoplasm, it has been demonstrated that mesothelioma cell lines are actually more responsive to ionizing radiation in vitro than non–small-cell lung cancer cell lines. External beam radiation therapy for mesothelioma is, however, somewhat limited by the large treatment volumes required and the radiation sensitivity of the surrounding organs (heart, lung, esophagus, spinal cord). Although palliative radiotherapy with an attempt to treat the entire involved pleural surface is technically challenging, and associated with a high risk of radiation pneumonitis, myelitis, hepatitis, and myocarditis, it can provide effective local palliation in up to 50% of patients.[90]

There are anecdotal reports of long-term survivors following high-dose external beam irradiation, and even after intrapleural administration of radioactive isotopes. However, most studies have shown no significant effect upon overall survival in patients with mesothelioma.[91]

Radiation therapy may play a role by preventing chest wall recurrences after invasive procedures, and in improving local control after pleurectomy or extrapleural pneumonectomy (EPP).[4,91–93] Mesothelioma frequently implants along the tracts of biopsies, chest tubes, thoracoscopy trocars, and surgical incisions, producing uncomfortable subcutaneous nodules. This can be prevented with prophylactic radiotherapy. In a small randomized trial, Boutin et al. demonstrated that 21 Gy administered in three daily fractions, 10 to 15 days after thoracoscopy, decreased local recurrence from 40% to 0%.[94] These findings have been confirmed by other investigators as well.

Multimodality approaches commonly include adjuvant radiation following surgery, although there are no randomized trials that demonstrate its efficacy. Because the lung remains in place after pleurectomy, radiotherapy doses must be lower than when EPP is performed. The Radiation Oncology group at The University of Texas MD Anderson Cancer Center reported encouraging results using intensity-modulated radiotherapy (IMRT) following extrapleural pneumonectomy.[95,96] Employing careful treatment planning and IMRT, radiation doses of up to 50 to 60 Gy were possible without severe toxicity. With the combination of EPP and IMRT, local recurrences after surgery were virtually eliminated; however, novel distant disease patterns have begun to emerge. These data suggest that the combination of EPP and IMRT requires an additional treatment modality (i.e., chemotherapy or immunotherapy) to limit distant tumor growth. Although IMRT following EPP appeared to be more effective for local disease control in this initial series, a second series from the Dana-Farber Cancer Center suggested there was a significant increase in severe toxicity. In that report, 6 of 13 patients developed fatal pneumonitis in the contralateral lung.[97] More recent studies have demonstrated safety and efficacy of IMRT, either after EPP or in the adjuvant setting post–radical pleurectomy in the presence of an intact lung.[98–100] Novel forms of radiation therapy, including proton beam therapy, are currently under investigation for treatment of mesothelioma.[101,102]

Though not a traditional form of radiation therapy, there has also been interest in utilizing tumor treating fields (TTF), a technology that uses alternating electric fields to produce an antimitotic effect. The STELLAR trial was a phase 2, multicenter, single-arm trial combining TTF with standard-of-care chemotherapy (pemetrexed and cisplatin or carboplatin) as first-line treatment for unresectable malignant pleural mesothelioma. Of note, the study population had a high proportion of patients with non-epithelioid histology, and yet an overall survival of 18.2 months was achieved. This survival outcome was superior to historic controls of standard-of-care chemotherapy alone, and prompted FDA approval for TTF in this setting under a humanitarian device exception.[103] Caveats to implementation of TTF as in the STELLAR trial include the absence of a control arm from the trial, as well as the fact that the device is worn in the form of an external vest with a battery pack worn for approximately 18 h per day, which may affect quality of life for patients receiving this therapy.

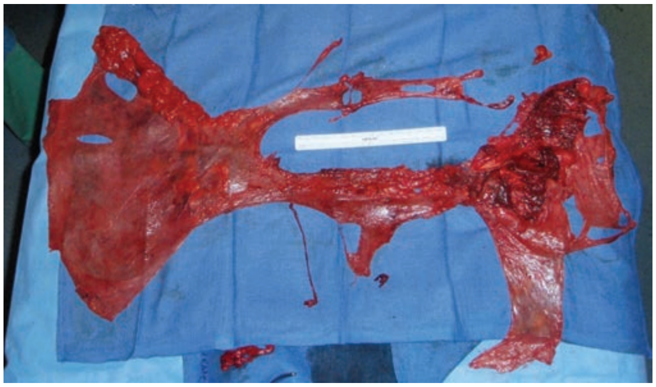

Figure 78-7 Gross photograph of a surgically resected pleurectomy/decortication specimen from a patient with malignant pleural mesothelioma. This involves the removal of the diseased pleura as an attempt to free the underlying lung to allow it to expand more freely. The steps involved are usually (1) incision and exposure of the parietal pleura, (2) dissection of parietal pleura from endothoracic fascia, diaphragm, and mediastinum, (3) incision of the parietal pleura and exposure of the visceral pleura, (4) decortication of the visceral pleura, and (5) reconstruction.

Surgical Approaches

Although associated with substantial morbidity, surgical management of mesothelioma has made significant strides in palliating the major symptoms of the disease, as well as potentially offering some improvement in survival for highly selected patients. The increased use of VATS, in conjunction with novel biomarkers, has facilitated early diagnosis of mesothelioma in more patients, at which point they may be candidates for more aggressive attempts at "definitive" surgical treatment (along with neoadjuvant/adjuvant therapies). However, definitive surgical intervention is only possible in a small percentage of patients. Furthermore, fewer than 25% of those who undergo aggressive surgical intervention will be alive at 5 years, and even fewer will be disease free at that timepoint.[104] The vast majority of pleural mesothelioma patients have locally advanced disease at the time of presentation, which, along with advanced age and/or other comorbid medical illnesses, often precludes aggressive surgical intervention.

EPP is a radical surgical procedure involving complete removal of the ipsilateral lung along with the parietal and visceral pleura, pericardium with portions of the phrenic nerve, and the majority of the hemidiaphragm (Fig. 78-7 and Video 78-1). EPP achieves

Video 78-1 Video recording from intraoperative thoracoscopic view of radical pleurectomy for malignant pleural mesothelioma performed through a thoracotomy incision. This surgical therapy for MPM is an alternative to extrapleural pneumonectomy. The procedure often takes up to several hours and involves extrapleural dissection, dissection of the diaphragm and pericardium, visceral pleurectomy, and lymph node dissection. *Video available on AccessMedicine.com.*

the greatest degree of cytoreduction and, because the lung has been removed, allows higher radiation doses to be delivered to the ipsilateral hemithorax. It is the only debulking procedure possible when a thick tumor rind obliterates the pleural space. There is a small group of long-term survivors following EPP when it is a component of a multimodality treatment program, suggesting that this procedure may alter the natural history of the disease in appropriately selected patients with early-stage disease.[105] Unfortunately, the benefits of EPP with adjuvant chemotherapy ± local radiotherapy are limited to otherwise healthy patients with early-stage disease, epithelioid histology, and no mediastinal lymph node involvement. Patients with biphasic or sarcomatoid histology and/or mediastinal or hilar node positivity have an ominous prognosis.[93,106]

EPP alone is an excellent means of palliating the profound dyspnea and orthopnea associated with the severe ventilation/perfusion mismatch resulting from lung encasement by mesothelioma. However, EPP alone has no influence on survival in the absence of adjuvant therapy.[107,108] In most EPP series, median survival from surgical debulking alone is less than 2 years, and 10% to 20% of patients are 5-year survivors. Biphasic/sarcomatoid histology and/or involvement of mediastinal lymph nodes confer a poorer prognosis and lack of demonstrable survival benefit from surgical intervention.

Several approaches for adjuvant therapy in conjunction with EPP have been studied. Investigators at Brigham and Women's Hospital have combined EPP with sequential postoperative chemotherapy and up to 55 Gy of adjuvant radiation therapy to the postoperative hemithorax.[109] More recently, the Brigham Thoracic Program has been investigating the role of hyperthermic intracavitary chemotherapy as an adjuvant to maximal cytoreductive surgery, in combination with hemithoracic irradiation and systemic chemotherapy.[110,111] In addition, several investigators have evaluated the utility of post-resectional photodynamic therapy (PDT) with or without adjuvant chemotherapy or immunotherapy.[112] One randomized trial conducted by Pass et al. at the National Cancer Institute failed to confirm any benefit for adjuvant PDT compared with surgery alone.[113,114] Novel photosensitizers are currently under study that may provide better local control, decreased photosensitivity, and perhaps improved induction of systemic antitumor immune responses. Other novel multicenter clinical trials combine maximal surgical debulking with adjuvant IMRT or alternatively assess the role of neoadjuvant chemotherapy prior to cytoreductive surgery to improve long-term outcomes. EPP in these contexts is designed as a cytoreductive, not a curative procedure.[115–117]

Parietal pleurectomy, that is, open surgical stripping of the pleura from the apex of the lung to the diaphragm, is more successful than talc pleurodesis in reducing the recurrence of pleural effusion in mesothelioma (Fig. 78-8). Thoracoscopic pleurectomy has been employed to achieve similar results as the open procedure, but with less morbidity.[92,118]

Complete parietal and visceral pleurectomy, referred to as extended pleurectomy/decortication or radical pleurectomy (EPD/RP), is designed to achieve maximal cytoreduction while leaving the ipsilateral lung intact. It involves complete resection of the entire parietal and visceral pleural including the diaphragmatic pleura and extends into the hilum to resect the pleural surfaces of the interlobar fissures. Some surgeons performing EPD/RP will also resect portions of the diaphragmatic musculature as well as the ipsilateral parietal pericardium. EPD/RP includes extensive dissection and removal of mediastinal, hilar, intercostal, and internal mammary lymph nodes. Although the procedure has not been shown by itself to prolong survival in patients with mesothelioma, it has largely become standard of care for surgical treatment of resectable malignant pleural mesothelioma.[119] A retrospective analysis of patients who underwent EPD/RP demonstrated a mean overall survival of 20.7 months, with the subgroup who achieved macroscopic complete resection surviving for 23.2 months, suggesting that durable responses may be attainable with less invasive surgical strategies.[120] There have been no prospective head-to-head trials comparing outcomes of EPD/RP with those following EPP, but several retrospective studies have demonstrated better survival for mesothelioma patients who underwent EPD/RP compared with those treated with EPP despite a higher rate of local recurrence.[121,122] There is an ongoing trial in the United Kingdom comparing radical pleurectomy plus pemetrexed/platinum agent versus chemotherapy alone, which will likely help dictate the future utility of this procedure.[123]

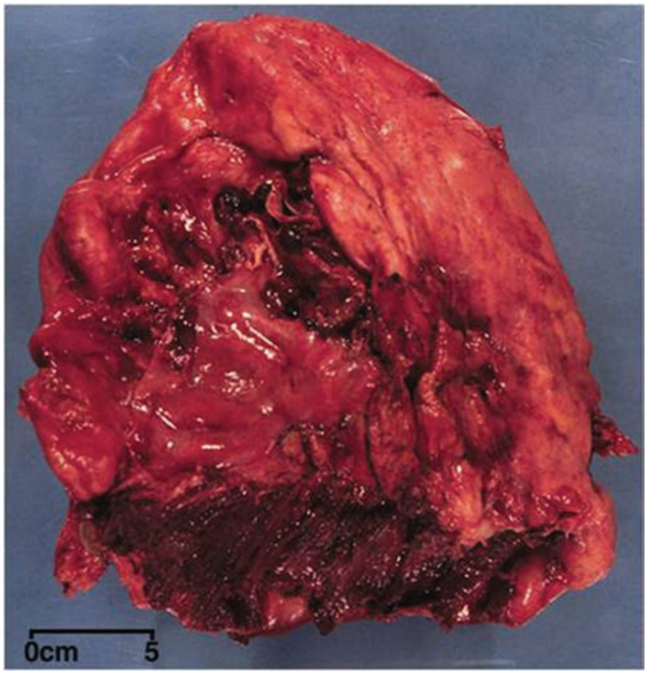

Figure 78-8 Gross photograph of a surgically resected extrapleural pneumonectomy specimen from a patient with malignant pleural mesothelioma. The specimen includes the completely removed lung along with the parietal and visceral pleura, pericardium with portions of the phrenic nerve, and the majority of the hemidiaphragm.

Investigators have evaluated the combination of EPD/RP with postoperative intrapleural radiation therapy, external beam irradiation, and/or systemic chemotherapy.[124–127] One single institution study reported a median survival of 22.5 months and a 2-year survival rate of 41% in a group of 27 patients, predominantly with the epithelioid subtype.[124,126]

There have been several recent reports describing EPD/RP as the cornerstone of multimodality treatment with various adjuvant intraoperative therapies such as intrapleural PDT,[128] intrapleural hyperthermic chemotherapy (cisplatin, gemcitabine),[129] and hyperthermic perfusion with povidone-iodine.[130] Hyperthermia is believed to disrupt intercellular bridges to allow for greater direct reach of chemotherapy to distant microscopic foci of tumor cells, as well as possibly synergizing with cytotoxic agents to facilitate tumor cell death. Many trials combining EPD/RP pleurectomy with intrapleural hyperthermic cisplatin have been published with attainment of durable responses with mean overall survival >20 months, improvement in postoperative functional status versus EPP, and the ability to concentrate cisplatin in the pleural space while allowing much lower serum levels of cisplatin to reduce systemic adverse effects.[131–133] Intrapleural hyperthermic therapeutics have also been administered in association with IMRT in the presence of intact lung with demonstration of preserved/improved pulmonary function. In all cases, adjuvant chemotherapy was administered, unless patients had received preoperative (neoadjuvant) chemotherapy.

Management of Pleural Effusions

The most common and discomforting symptom in mesothelioma is debilitating dyspnea from large, unilateral pleural effusions. A reasonable palliative approach is complete drainage of the pleural effusion by tube thoracostomy or VATS and instillation or insufflation of a sclerosing agent into the pleural space to induce pleurodesis. At present, the most widely used compound for pleurodesis is sterile, asbestos-free talc, administered either as a powder or slurry.[134,135] Thoracoscopic application (poudrage) may be more successful than other methods of pleurodesis (e.g., by tube thoracostomy). The effect of talc may be enhanced by an ability to induce apoptosis in some mesothelioma cell lines in vitro.[136] Interestingly, there have been reports of prolonged survival in mesothelioma patients after talc pleurodesis with no other active therapy for the disease.[137] Rintoul et al. performed a randomized trial (Meso-VATS) comparing talc pleurodesis with partial pleurectomy via VATS for the management of pleural effusions in patients with mesothelioma. The results demonstrated no significant difference in survival between the groups, but the VATS group experienced significantly longer hospitalization and more postoperative complications.[138]

Entrapment of the lung by a thick visceral pleural peel of tumor compromises the efficacy of pleurodesis in patients with pleural mesothelioma. In the setting of trapped lung, the use of a semipermanent tunneled intrapleural catheter for intermittent drainage of recurrent effusions provides excellent palliation of dyspnea.[139,140] Pleuroperitoneal shunting, an alternative approach for dealing with lung entrapment in pleura mesothelioma, carries the overt risk of malignant seeding of the peritoneal cavity. The primary concerns regarding the use of tunneled pleural catheters in mesothelioma are the development of tumor implants at the insertion site or along the subcutaneous tunnel, as well as the risk of chest wall and/or intrapleural infections with long-term use of the catheter. Recent reports of tunneled catheters for mesothelioma show equivalent results for the control of effusions compared with talc slurry pleurodesis.[141,142] Therefore, these catheters should be considered for management of symptomatic effusions in patients with mesothelioma, even in those whose lungs are able to expand.

Treatment of Nonpleural Forms of Mesothelioma

Patients with peritoneal mesothelioma, the second most common form of mesothelioma after the pleural form, most often present with abdominal pain, distention, and ascites. In addition, peritoneal mesothelioma can be associated with hypoalbuminemia, night sweats, inguinal and umbilical hernias, and hypercoagulability. Laboratory investigation shows an increased platelet count in about 50% of patients, and many patients also have elevation of the tumor marker CA-125. As with pleural mesothelioma, single-agent chemotherapy for the peritoneal variant has a response rate of only 10% to 15%, whereas combination chemotherapies, such as cisplatin plus pemetrexed, improve the response rate to about 25%. Immunotherapeutic agents such as interferons (IFNs) and various cytokines may have a role in treating this disease, especially when the extent of disease is minimal.[143–145]

Patients diagnosed with peritoneal mesothelioma appear to have a better overall prognosis relative to the pleural form. This may reflect the technical ease of delivery of intraperitoneal chemotherapy as well as the capacity for multiple resections/debulking of peritoneal masses. One-third of patients with peritoneal mesothelioma in a Dana-Farber phase 2 series of 25 patients remained disease free at 2 to 3 years after treatment.[144] Multimodality treatment protocols include surgical debulking followed by intraperitoneal administration of cisplatin, doxorubicin, and IFN-γ, second laparotomy with attempted resection of any residual disease, and intraoperative hyperthermic perfusion with cisplatin and mitomycin followed subsequently by whole abdominal radiotherapy. In one study, the median overall survival of the 27 patients treated was 68 months.[146]

Pericardial mesothelioma is quite rare but characteristically presents with pericardial effusion and, often, tamponade physiology. Mesotheliomas of the tunica vaginalis are even less common than the pericardial variant but typically present with a bloody hydrocele. There is no effective therapy for mesothelioma of the pericardium or tunica vaginalis other than palliation; these neoplasms share the dismal prognosis of the pleural form of the disease.

Novel and Evolving Therapeutic Approaches

Despite the small but significant improvement in survival achieved with intensive multimodality therapy for mesothelioma, it is obvious that less morbid, more effective interventions are needed. Many investigators, focusing on the hemithorax as the primary site of disease, have attempted to treat this disease primarily by direct instillation of chemotherapeutic and other compounds into the pleural space, but with minimal success. Based on anecdotal reports that mesothelioma patients with greater amounts of intratumoral lymphocytic infiltration had improved median survival rates,[147] several groups have looked at immunotherapy as an alternative means of achieving better tumor response rates.

Immunotherapy

The use of compounds to stimulate an antitumor immune response against pleural malignancy stemmed from the observation that patients who developed empyemas post-thoracotomy for primary lung carcinoma had improved survival rates.[148,149] Subsequently, intrapleural bacille Calmette-Guérin (BCG) was studied as a surgical adjuvant, but no significant benefit was seen.[150] More recently, clinical trials for multiple primary solid tumors have studied the use of a *Listeria* vaccine that expresses mesothelin, otherwise known as CRS-207. A phase 1 trial of CRS-207 in patients with advanced cancers, including mesothelioma, demonstrated a dose-dependent inflammatory response, as well as mesothelin antigen–specific T-cell activation.[151] A subsequent study with CRS-207 in combination with chemotherapy in mesothelioma has since been halted due to a similar study in pancreatic cancer obtaining negative results.[152,153] However, given the significant and specific immune activation with CRS-207, there may be potential in combining this vaccine with systemic immunotherapy.

Several systemic immunotherapies have been administered to patients with mesothelioma, including IL-2 and IFN-γ, both of which demonstrated limited efficacy and significant side effects. The major disadvantage to using these cytokines is that they can also have anti-inflammatory end-results. For example, IL-2 can support the activity of T regulatory cells. Additionally, IFN-γ can lead to downregulation of MHC molecules and upregulation of checkpoint ligands on tumor cells. Subcutaneous IFN-α-2a was found to have some efficacy; in a study of 25 patients, 1 complete response and 3 partial responses were documented, and the therapy was well tolerated.[154] One European phase 1/2 study of intrapleural IL-2 administered by continuous infusion via an intrapleural catheter revealed a 19% partial response rate with marked dose-related toxicity, primarily the development of ipsilateral empyemas. Of note were the high ratios of intrapleural/systemic IL-2 levels approaching 1000:1, particularly in the highest doses.[155]

Boutin et al. in Marseilles, France, pioneered the intrapleural administration of immunostimulants to treat mesothelioma and demonstrated significant local tumor responses with both intrapleural IL-2 and intrapleural IFN-γ. Most impressive were the results of intrapleural IFN-γ in patients with early-stage mesothelioma (Butchart stages I and II). A total of 89 patients were treated over 46 months with an overall response rate of 20%. In all, 8 patients had histologically confirmed complete responses, and 9 had partial responses with greater than 50% reduction in tumor volume. Overall, patients with stage I disease had a response rate of 45%. The effectiveness of IFN-γ against mesothelioma was thought to be mediated in part by direct inhibitory effects on mesothelioma cell growth as well as by decreased intrapleural IL-6 production, with resultant activation of tumor-directed macrophages and cytotoxic T lymphocytes.[156,157] Other groups have demonstrated only limited activity with the combination of intrapleurally administered autologous-activated macrophages and IFN-γ. The overall response rate was 11% in a trial of 19 patients, with 1 patient having a partial response that lasted for 30 months.[158]

Immunotherapy trials in Australia demonstrated tumor regression with repeated intralesional injection of granulocyte-macrophage colony-stimulating factor (GM-CSF), but with substantial complications related to the catheters used for cytokine instillation.[159–161]

Over the past decade, implementation of immune checkpoint inhibitors (CPI) has changed the treatment paradigm of mesothelioma. The landmark phase 3 trial CheckMate 743 demonstrated significantly increased survival with first-line combination PD-L1/CTLA4 CPI versus standard-of-care chemotherapy in patients with untreated unresectable mesothelioma, particularly in those with sarcomatoid and biphasic histologic subtypes and >1% PD-L1 expression. This combination regimen was approved by the FDA in 2020—the first immunotherapy regimen approved for the treatment of mesothelioma of any stage. Interestingly, there was no statistical difference in severe adverse events between both experimental groups, despite high rates of immune-related adverse events in previous trials with combination immunotherapy in other tumor types.[162]

Prior investigation of single-agent regimens as second-line therapy with CTLA-4 inhibition, such as with the CPI tremelimumab, in pretreated patients did not demonstrate significant improvement in outcomes despite initial promise in phase 2 clinical trials.[163] However, PD-1/PD-L1 inhibition has shown stronger evidence for efficacy in mesothelioma. Single-agent treatment with nivolumab in previously treated patients demonstrated improved survival and resulted in FDA approval as second-line therapy.[164] Treatment with avelumab, a PD-L1 inhibitor, in previously treated patients and first-line treatment with durvalumab, a PD-1 inhibitor, in combination with standard-of-care chemotherapy demonstrated durable responses in early-stage trials, prompting ongoing study.[165,166]

Currently a large degree of research effort is being spent to answer two questions for CPI in mesothelioma: (1) Why do the majority of mesothelioma patients receiving CPI not respond? and (2) What biomarkers can accurately identify mesothelioma patients who will respond to CPI?

"Targeted" Therapy

The presence of platelet-derived growth factor (PDGF) and epidermal growth factor (EGF) pathways in some mesothelioma cell lines in vitro suggested that novel inhibitors of these pathways might prove useful clinically, either as monotherapy or in combination with chemotherapy. Unfortunately, early-phase clinical trials in mesothelioma of imatinib mesylate and gefitinib (and erlotinib), inhibitors of the tyrosine kinases essential to PDGF and EGF signaling, respectively, failed to demonstrate any significant clinical benefits.[167–169] Clinical trials have been conducted with other novel targeted agents, such as the antiangiogenic agents bevacizumab and thalidomide, and the copper-chelating agent tetrathiomolybdate, which depletes copper, a key cofactor in tumor angiogenesis. Only the latter compound has shown any demonstrable benefit to date in human trials.[170–172] Currently, there are several clinical trials of combinations of targeted agents to see if they may have synergistic effects upon growth of mesothelioma in patients with advanced disease.

Other pathways of cellular metabolism also have been targeted in mesothelioma, one of the most promising of which is intracellular utilization of arginine. Szlosarek et al. published the first trial examining arginine deprivation in cancer, specifically treating patients with arginosuccinate synthetase 1 (AS1)-deficient tumors with pegylated arginine deiminase (ADI-PEG20). In comparison with standard supportive care, they demonstrated an increased progression-free survival, and the subgroup with at least 75% reduction in AS1 had improvements in both progression-free survival and overall survival.[173] Beddowes et al. performed a dose escalation study with pegylated arginine deiminase in combination with standard-of-care chemotherapy in patients with mesothelioma or non–small-cell lung cancer, and no dose-limiting toxicity was noted, while achieving partial responses in 7 of 9 patients.[174] These studies have increased interest in targeting this pathway to treat mesothelioma, and there is an ongoing multicenter, randomized, controlled trial studying the combination of ADI-PEG20 with standard-of-care chemotherapy in mesothelioma.[175]

There have also been several trials evaluating tyrosine kinase inhibitors that are FDA-approved for other indications. A phase 2 trial of pemetrexed/platinum agent plus/minus nintedanib in patients with epithelioid and biphasic mesothelioma demonstrated significantly increased progression-free survival. However, a phase 3 trial with nintedanib did not demonstrate a significant improvement in outcomes.[176,177]

Gene Therapy

In the absence of other effective, nontoxic therapies for malignant mesothelioma, several groups of investigators have looked to the newly evolving technologies of gene therapy for new treatment modalities.[178] Gene therapy is attractive because mesothelioma remains localized initially and pleural access to the tumor is easy and safe. A large number of approaches have been used in cell culture and in animal models. Gene therapy vectors have included liposomal/DNA complexes and modified herpes, vaccinia, and adenoviruses. Transgenes have included suicide genes, cytokines, tumor suppressor genes (e.g., p53), and proapoptotic genes. Studies have also been done using replication-restricted, tumor-selective adenoviruses and herpes viruses as well as carrier cells, such as modified ovarian carcinoma cells.[178,179] Danson et al. conducted a phase 1/2A clinical trial with intrapleural administration of HSV1716, a replication-restricted strain of herpes simplex virus without expression of RL1, allowing it to only replicate in dividing cells, in 13 patients with mesothelioma. The patients subsequently demonstrated seropositivity to the virus, viral replication, development of antitumor antibodies, and short-term stabilization of disease in half the study participants without dose-limiting toxicities.[180] While there was not significant tumor response to this oncolytic virus alone, the significant immune activation may provide avenues of investigation to develop an adjunctive intrapleural/intratumoral therapy on top of systemic checkpoint inhibition.

Additional early phase 1 clinical trials of intrapleural gene delivery have been performed in patients with advanced mesothelioma. These include a "suicide" gene therapy strategy employing the instillation of recombinant adenovirus (rAd) genetically engineered to contain the herpes simplex virus thymidine kinase "suicide gene" (HSVtk).[181,182] The rationale for the suicide gene approach for mesothelioma was that administration of rAd.HSVtk into the pleural cavity would sensitize the cells to the normally nontoxic antiviral agent ganciclovir. The vector was well tolerated, gene transfer was seen at higher doses, and a number of patients had clinical responses, including patients with minimal radiographic evidence of disease 7 years after treatment, with no other intervening antineoplastic therapy. The HSVtk gene was also introduced into patients using an irradiated allogeneic ovarian cancer cell line. A phase 1 trial with intrapleural administration of an adenoviral vector expressing the HSVtk gene in combination with valacyclovir, celecoxib, and standard-of-care chemotherapy in patients with malignant pleural effusion caused by many different primary solid malignancies demonstrated durable responses in a subset of patients, and there are ongoing trials with gene-mediated cytotoxic immunotherapy in a variety of solid malignancies.[183]

A few early-phase trials have recently completed using adenoviral-mediated immunogene therapy delivering the cytokines IFN-α and IFN-β, which have a number of antitumor immune effects. The vector was well tolerated (most common adverse events were lymphopenia, hypoalbuminemia, hypotension, anemia, hypocalcemia, and mild cytokine release syndrome), resulted in detectable intrapleural levels of the interferon proteins in most patients, and was accompanied by antitumor immune responses in multiple patients. A number of patients with low tumor burdens had disease stability or clinical responses.[184–186]

A pilot study evaluating intrapleural Ad-IFN-α in combination with celecoxib and either first-line chemotherapy or second-line chemotherapy in previously treated patients demonstrated durable responses, with the first-line chemotherapy group attaining mean overall survival of 12.5 months, and the second-line chemotherapy group achieving mean overall survival of 21.5 months.[187] These results prompted further study in the INFINITE trial, a multicenter, randomized, controlled trial that recently halted accrual due to competing enrollment with other studies (NCT03710876).

Other gene therapy approaches have been studied by various groups attempting to achieve high-level expression of other immunostimulatory cytokines such as IL-2, IL-12, TNF, and GM-CSF. In addition, there are ongoing phase 1 trials of intrapleural delivery of oncolytic viruses, including measles, herpes simplex, and vaccinia viruses, all of which have shown significant antitumor activity against mesothelioma in vitro and in preclinical models.[178]

Adoptive Cellular Therapy

Adoptive transfer of T cells and other immune cells into patients after ex vivo expansion has demonstrated very promising results in diseases like malignant melanoma and leukemias. Groups have attempted to acquire tumor-reactive tumor-infiltrating lymphocytes (TILs) from mesothelioma samples, expanding them ex vivo, then reinfusing them back into the host with minimal success. Since this method utilizes polyclonal T cells, all of which may not be reactive to a patient's mesothelioma tumor, research efforts have been made to genetically tailor otherwise nonreactive T cells to target a specific mesothelioma's tumor-associated antigen. Researchers at the University of Pennsylvania and Memorial Sloan Kettering have successfully genetically modified T cells to express a chimeric antigen receptor (CAR) that recognizes the tumor antigen mesothelin through a single-chain formulation of the variable chain (scFv) of an antimesothelin antibody that activates the T-cell through a combination of internal signaling domains from the T cell receptor.[188,189] The mesothelin CAR T cells were able to eradicate large mesothelioma tumors in mice, and this has led to subsequent early-phase clinical trials assessing the feasibility and safety of multiple doses of CAR T cells reactive to mesothelin.

There have been two mesothelin-targeted CAR T cell trials recently published demonstrating the potential of this technology in mesothelioma. Haas et al. at the Abramson Cancer Center of the University of Pennsylvania reported the results of a phase 1 study of lentiviral-transduced mesothelin-directed CAR T cells in 15 patients with advanced solid cancers including mesothelioma.[190] This came after an initial test using multiple doses of mRNA-electroporated T cells with only transient CAR expression demonstrated safety in patients.[191] Of 15 patients, 11 demonstrated stable disease by Response Evaluation Criteria In Solid Tumors (RECIST) methodology after IV infusion of CART-meso cells, and only 1 patient experienced dose-limiting toxicity. CAR T-cells expanded in the periphery and reached peak levels by ~1 to 2 weeks post-transfer but were transient in persistence. Cyclophosphamide pretreatment improved persistence but not beyond 28 days. In 7 of 10 cases where posttreatment biopsies were obtainable, CAR DNA was detectable. These initial efforts were based on a monoclonal mouse–antihuman antibody (SS1) identified by Dr. Ira Pastan. Researchers have switched to a fully humanized construct in light of the demonstration of human–antimouse antibody responses with anaphylaxis in one patient.[192]

More recently, Adusumilli et al. at Memorial Sloan-Kettering Cancer Center published the results of a phase 1 trial of regional mesothelin-targeted CAR T-cell therapy in patients with malignant pleural disease, including mesothelioma (tumor cell mesothelin expression >10%), in combination with the anti–PD-1 agent pembrolizumab. The design for this trial was based upon preclinical murine studies that demonstrated limited antitumor activity of intrapleural CAR T-cell administration in mice with large tumor burdens mediated by mitigation of T-cell exhaustion with coadministration of systemic anti–PD-1 monoclonal antibody. This study has the distinction of being the first published trial of intrapleural CAR T-cell therapy in humans. Importantly, there were no dose-limiting toxicities, although several patients experienced cytokine release syndrome requiring hospitalization and IL-6 inhibition with tocilizumab. In this single-arm noncontrolled study, median overall survival after CAR T-cell treatment in patients with malignant pleural disease who received pembrolizumab was 23.9 months, with some associated dramatic responses on imaging.[193]

Other cellular therapies that are being investigated are injection of mesothelioma tumor lysate-pulsed dendritic cells and lymphokine-activated killer cells.[194,195] A single cohort of 10 patients with previously treated mesothelioma were treated with dendritic cell vaccination and cyclophosphamide, and 8 of 10 patients achieved disease control, 2 of whom had durable responses and were still living at 55 months. These results prompted an ongoing phase 3 trial evaluating standard-of-care chemotherapy plus/minus dendritic cell vaccination (NCT02649829).

SOLITARY FIBROUS TUMOR OF THE PLEURA

Solitary fibrous tumors of the pleura had been previously referred to in the literature as "benign mesothelioma." This is an inappropriate expression, both in terms of histogenesis and because of the potential for confusion with malignant mesothelioma. Solitary fibrous tumors have also been called localized fibrous tumor because of the occasional incidence of multiple masses. Solitary fibrous tumor is a mesenchymal tumor of fibroblastic origin, and similar tumors have been described in other extrathoracic sites.[34] It is important to note that there is no significant association of solitary fibrous tumors with asbestos exposure or other environmental agents. Although the peak age range of affected patients is similar to that of mesothelioma (40–70 years), solitary fibrous tumors can affect patients of all ages, including children as young as 5 years old.

Clinical Presentation

Patients with solitary fibrous tumors of the pleura are usually asymptomatic and are diagnosed incidentally by routine chest radiography, but they can present with nonpleuritic chest pain, dyspnea, cough, or pleural effusion. A significant proportion (up to 40%) of patients present with symptomatic hypoglycemia, thought to be secondary to elaboration of insulin-like growth factors. Clubbing of fingers and toes is common, as are diffuse arthralgias, but the incidence of pulmonary hypertrophic osteoarthropathy is controversial.[196–199]

Radiography

Solitary fibrous tumors typically present radiographically as large, rounded, well-circumscribed, pleura-based masses, but occasionally they can appear to be intraparenchymal. Some of these masses can be very large (>30 cm in diameter) and can cause clinically significant compression of the lung. About 17% present with an ipsilateral pleural effusion.[197,200]

Gross Pathology

The typical solitary fibrous tumor of the pleura arises from a pedicle off the visceral pleura surface and rarely invades beyond the visceral pleura itself (Fig. 78-9A). The tumors are usually well-circumscribed, firm, often pedunculated masses that vary in size from 1 cm to more than 30 cm in diameter. When sectioned, the cut surface has a whorled appearance. Attention should be paid to areas of hemorrhage or necrosis. Malignant solitary fibrous tumors have been described, although they are less frequent.[34,201–203]

Microscopic Pathology

Histologically, solitary fibrous tumors have what has been described as a "patternless pattern" (Fig. 78-9B). Sections typically show alternating areas of hypocellularity and hypercellularity with short fascicles of interlacing spindle cells, creating a storiform pattern. These fascicles are interspersed between areas of variably collagenized tissue. A hemangiopericytoma-like branching vascular pattern is also quite typical. Histologic criteria that may predict a malignant course include increased cellularity, infiltrative growth, cytologic atypia, necrosis, and a mitotic rate with greater than 2 mitoses/mm^2.[34] Immunohistochemical stains confirm the diagnosis. These tumors are CD34 (Fig. 78-9C) and STAT6 positive but CK negative. Expression of CD34 and STAT6 may be lost in dedifferentiated solitary fibrous tumors, and therefore the diagnosis might require the exclusion of other malignant tumors such as malignant mesothelioma, monophasic synovial sarcoma, and peripheral nerve sheath tumors.

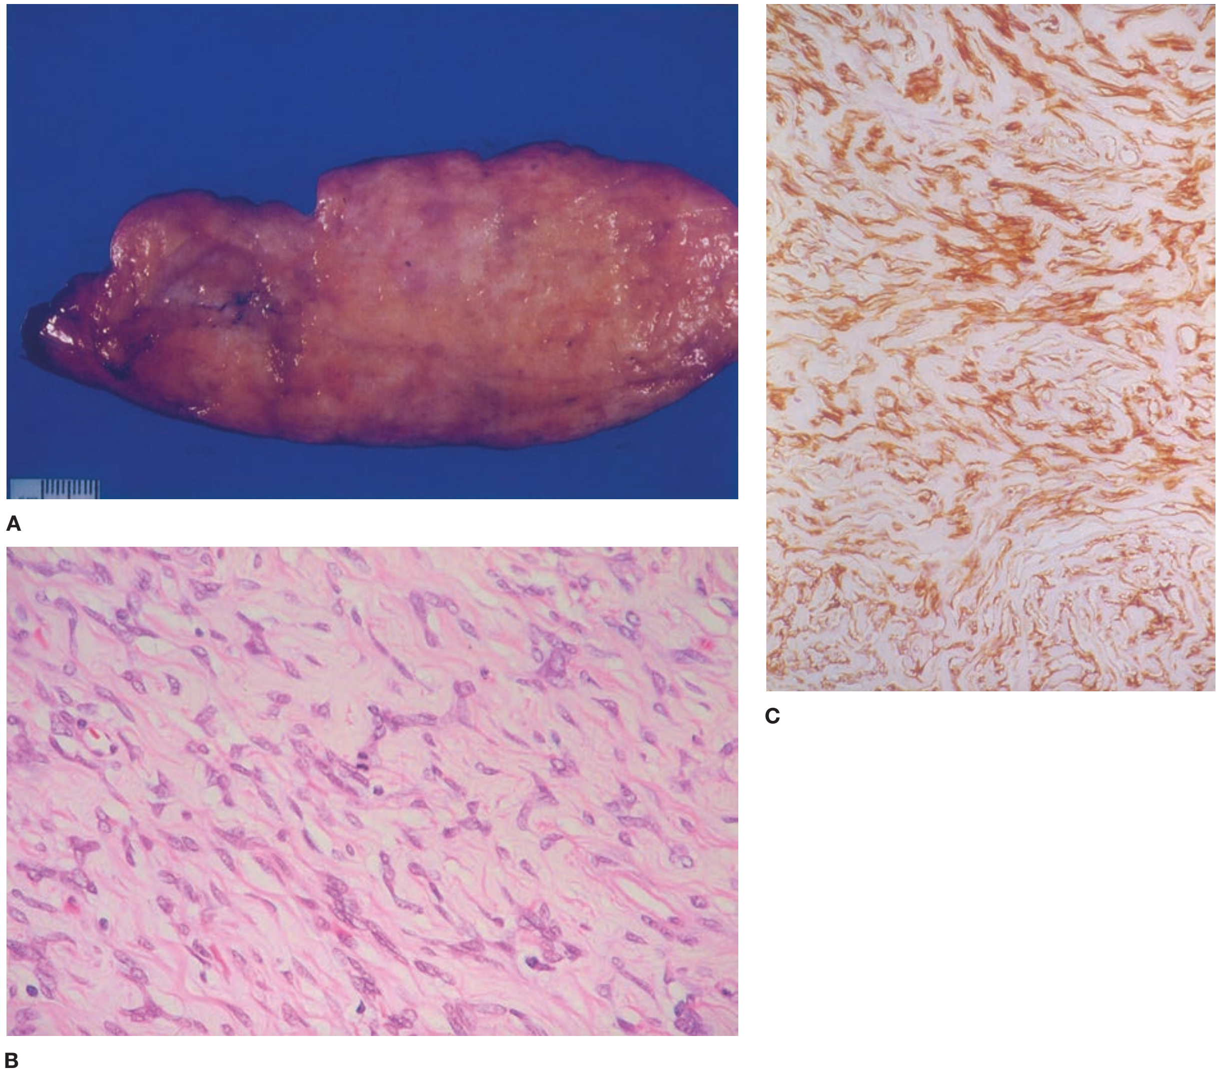

Figure 78-9 **A.** Gross photograph of a surgically resected, solitary, benign pleural fibrous tumor. Note the well-circumscribed nature of this firm, slightly lobulated mass with its smooth-cut surface and punctate areas of hemorrhage and necrosis. **B.** Photomicrograph of a typical solitary fibrous tumor demonstrating the "patternless pattern" (H&E, ×400). **C.** Photomicrograph of a section of solitary fibrous tumor stained with an antibody directed against CD34, a cell surface marker found commonly on endothelial cells and some smooth muscle and vascular tumors (×400). Positive staining for CD34 helps distinguish these lesions from mesotheliomas and other pleural neoplasms. *(Reproduced with permission from Dr. Matt van de Rijn, Department of Pathology and Laboratory Medicine, University of Pennsylvania Medical Center, Philadelphia.)*

Treatment

Surgical resection of solitary fibrous tumors of the pleura is curative with little risk of recurrence. There is typically a discrete separation between the tumor and underlying compressed lung, so extensive pulmonary resection is usually unnecessary. Some tumors may require a limited chest wall resection. A small percentage of patients develop recurrences several decades after surgical resection and may die from extensive local disease. Some of these recurrent fibrous tumors of the pleura demonstrate more aggressive histologic features but are often successfully cured by surgical excision, in particular the pedunculated lesions.[197–199]

Even with malignant solitary fibrous tumors of the pleura, complete resection portends a favorable prognosis in most patients. In one series, complete resection was achieved in more than 90% of patients, with disease-free survival rates of 72% and 61% at 5 and 10 years, respectively.[199]

OTHER PRIMARY PLEURAL TUMORS

As discussed in the differential diagnosis of sarcomatoid mesotheliomas, there are other relatively rare malignant mesenchymal tumors that can be primary within the pleura. These tumors include vascular tumors (pleural epithelioid hemangioendothelioma/angiosarcoma) and synovial sarcoma.

Pleural epithelioid hemangioendothelioma is a malignant vascular tumor composed of epithelioid endothelial cells within a distinctive myxohyaline stroma.[34] The clinical presentation of patients with these tumors, as well as the radiographic features and gross appearance, are essentially identical to malignant mesothelioma. Patients present with diffuse pleural thickening, pleural effusion, and/or chest pain. Microscopic examination with the ancillary use of IHC is required for diagnosis. These tumors usually have a biphasic pattern with nests of epithelioid cells embedded within a spindle cell stroma. The epithelioid cells characteristically have intracytoplasmic vacuoles, and the associated stroma typically has a distinctive myxohyaline or chondroid appearance. As with malignant mesotheliomas, a tubopapillary pattern may also be present.

Vascular differentiation is demonstrated by strong positive staining with one or more endothelial markers (CD31, CD34, and ERG), although there is significant variability in expression. CK positivity may also be present and can be misleading if the diagnosis of a vascular tumor is not considered. The diagnosis can be confirmed by identification of the *WWTR1-CAMTA1* or *YAP1-TFE3* fusion transcripts. These tumors behave aggressively, with most patients dying of disease within 1 year.[34] Angiosarcoma of the pleura has a similarly aggressive clinical course.

The diagnosis of pleural synovial sarcoma has improved with increased awareness and the greater availability of molecular testing for its distinctive X:18 translocation that now can be demonstrated in formalin-fixed paraffin-embedded tissue. Synovial sarcomas present as either a biphasic epithelioid and spindle-cell tumor or as a monophasic spindle-cell tumor. In either instance, synovial sarcoma can be mistaken for malignant mesothelioma or a pulmonary sarcomatoid carcinoma. On average, patients tend to be younger than those with malignant mesothelioma, but there is a wide reported age range that encompasses older patients into their eighth decade. There is a similar overlap in clinical presentation with malignant mesothelioma that includes chest pain, pleural effusions, dyspnea, and pneumothorax. Although pleural synovial sarcoma is more commonly a localized, solid tumor, diffuse pleural thickening does occur. The tumors can be quite large (mean size of 13 cm) and can have areas of necrosis and cystic degeneration. There are some histologic features that are suggestive of synovial sarcoma, in particular its long interweaving fascicles, but the immunohistochemical profile of these tumors is not distinctive. The epithelioid component may show focal positive staining for CK, EMA, CEA, or BER-EP4. The spindle-cell component may express calretinin. Confirmation of the diagnosis requires molecular testing for the X:18 translocation. Pleural synovial sarcoma is an aggressive disease with a generally poor prognosis.[204–209]
